Dr. T. Gaillard Thomas, of New York, presented a communication entitled

ETIOLOGY, PATHOLOGY, AND TREATMENT OF FLEXIONS OF THE UTERUS.

He said that he deemed it an honor to be able to read his essay in the presence of one who had done so much in this line—Graily Hewitt, of London. A subject so trite he feared might surprise his hearers, but too much has been done and said about the newer operations in gynecology. He gave the following varieties: 1. Anteflexion of the body, the cervix in the normal position. 2. Anteflexion of the cervix, body in the normal position.

3. Anteflexion simultaneous of both the body and the cervix. 4. Anteflexion irreducible. 5. Anteflexion reducible. At the age of ten, when the uterus is developing to take on the function of puberty, faulty dressing or a long-continued full rectum often brings on this complication. A decided anteflexion between fourteen and fifty is a grave affair. The notion that anteflexion is normal or harmless is fruitful of much mischief. A flexion of the body will sometimes occur so high up that it will be overlooked by one who expects the flexion to occur invariably at the internal os. He then gave some experience from his daily life in the treatment of this trouble, which was of interest. A patient will come to me from Dr. A, who has told her that anteflexion is not an important factor in her case, and has treated her for two years without benefit by means of internal remedies. Dr. B has used injections and electricity: Dr. D, for eighteen months, with like success. Dr. C has diligently inserted medicated tampons and pessaries for a year, and no improvement. They all did the best they could, according to their light, but they did not cure their patient. He who always throws pessaries aside should not be allowed to practise. One who does not know how to use them should be shunned. The profession is divided into two classes—those who know how to use pessaries and those who do not. He prefers glass as an intra-uterine stem in all cases. In his operation he anæsthetizes the patient and then fills the vagina with antiseptic fluid. He then pulls the cervix down into this fluid and holds it there, and makes posterior section. In some cases this posterior section is not sufficient, and removal of the cervix is necessary, after vain efforts to reduce the anteflexion. Would that I could color this essay, he said, with the roseate hue which accompanies many essays, but I cannot. I often even fail to palliate the trouble, yet I have my chagrin soothed by the certain knowledge that I have not put my patient to great expense and danger.

Dr. Graily Hewitt, of London, said he found that in some cases it was necessary to dilate the cervical canal and relieve some contractions. He thought that what Dr. Thomas had said in regard to position embodied the whole truth.

Dr. Priestley, of London, said that the question of flexions was such a mixed one that it was difficult to know what to believe. He wished some one would give us complete statistics as to the occurrence of the trouble and to the results of treatment. Dr. West holds that flexion of the uterus, without congestion or inflammation, does not give rise to any symptoms. We need statistics on this subject, and he who will give us the proper way to treat this trouble will do much for his profession.

Dr. Ely Vander Warker, of Syracuse, N. Y., said that ten years ago he read a paper before this Society and advised the use of the intrauterine stem. He was strongly condemned by Dr. Thomas and others. He was now glad to see Dr. Thomas take back much of his sayings at that time. Had one of his patients then treated with intrauterine stems died, he would not have found one of his colleagues to defend him from the charge of manslaughter, nor could he have found an authority in this country on whom he could lean for support. He was amazed to hear that anyone could not see symptoms after flexion.

Dr. Robert Battey, of Rome, Ga., delivered the

PRESIDENT'S ADDRESS.

He did not treat especially of any scientific subject but rather turned his remarks to the future action of the Society and its general welfare. In accordance with a petition signed by nearly every member of the Society, he had changed the place of meeting from Boston to Washington, so as to be with the Congress. The Society was organized alone for the advancement of science. There was in it no field for the parliamentarian or medical politician. He then took up the subject of our vacant chairs. The membership was first limited to 60, and after two attempts was changed to 100. Fifty-eight is the highest number yet enrolled on our list. In twelve years the membership has grown from 39 to 58; average number, 51. The attendance has grown from 19 to 44, with an average of 29. When we consider that the Society is made up of busy specialists in large and lucrative practice, who cannot leave without a considerable pecuniary loss, I think an average attendance of 29 out of an average membership of 51 is not bad. The attendance at New York was seventy per cent.; in other Eastern cities not much less. In Cincinnati and Chicago the per cent. of attendance was low. Hence the advisability of

MEETING IN SOME LARGE CENTRE OF POPULATION.

Two of our members have been present at all of the meetings, 2 at eleven and 10 at three. One fellow has contributed ten papers, another nine, two eight each. Only three of the older fellows have not read papers, but these have contributed largely to the interest of the discussions. Men grow old, weary, and worn, and we must look to the young for aid. In the past, America has been known as the home of gynecology, and at the present time no country can boast of more good workers in this field. Our Society is like the Federal officeholder in Washington—few die and none resign. Our forty-two vacant chairs might be filled by lowering the standard of admission, but this would be bad policy. They might be filled by invitation, as most good men are modest and do not like to push themselves forward, fearing they might not be welcome. The members in the different States could look up this matter and encourage good men to unite with us. If we do not try to fill up the vacant chairs, had we not better return the limit to 60, the original number? Two travellers find a pebble by the way side. One picks it up, admires its translucency and casts it aside; the other examines it,

SEES THROUGH ITS ROUGH EXTERIOR

the diamond, and polishes it, producing a brilliant jewel. One who in this day locks up in his bosom truths of so great benefit to suffering humanity is not deserving of recognition. In the words of a homely Southern wit, "If our hind-sight was as good as our fore-sight, it would be much better for us." It may be safe to ask if the *ipse dixit* of an operator years afterward can be accepted, concerning a certain operation, or the testimony of a patient after a like lapse of years as to what work was done in her abdomen while she was under the influence of an anæsthetic. Must we allow operators to bring in cases especially cooked for the occasion? Against such doings no honest man can stand. The speaker then discussed the legal side of limitation, and said there was need of a statute of limitation in medicine, to protect a true discoverer from the schemes of the dishonest. There is an unwritten law in the minds of honest medical men which in this day of medical journalism and medical societies prevents the dishonest ambitions of men going behind the records. The address was received with rounds of applause.

ASSOCIATION OF GENITO-URINARY SURGEONS.

Wednesday, September 19th—Second Day.

The following officers were elected:

President, Dr. Robert W. Taylor, of New York City; *Vice-President*, Dr. John P. Bryson, of St. Louis, Mo.; *Secretary*, Dr. Arthur S. Cabot, of Boston, Mass.

Dr. Francis S. Watson, of Boston, Mass., read a paper on

THE OPERATIVE TREATMENT OF HYPERTROPHY OF THE PROSTATE,

with stereopticon demonstrations of specimens, etc.

The author began by an enumeration of the operations in use for relief of the disease. The indications for operation were stated to be as follows: Very frequent urination, repeated attacks of retention, necessary catheterization, purulent or hemorrhagic cystitis, and *failure of palliative treatment.*

The status of expert surgical opinion of to-day was shown by many quotations, which demonstrated the fact that, while one surgeon advocates one operation, and one surgeon another, no one has as yet shown the reasons governing the choice of operation in individual cases. In other words, no rationale underlies the operative treatment.

The object of the paper was stated to be the formation of such a rational basis of treatment. To do this the author had to offer data of two sorts: 1. Anatomical, and, 2, clinical. The anatomical collection consisted of thirty-four specimens.

These were exhibited by the stereopticon.

The author emphasized, as being the three important elements in the choice of operation, anatomically speaking, the distance from the junction of the prostatic and membranous urethra to the most distant portion of the median enlargement within the bladder, which distance, for the sake of convenience, is called the *perineal* distance; second, the form of the median enlargement; and, third, whether the bladder is of small capacity and non-distensible, or, on the contrary, of large capacity and readily distensible. If the perineal distance just described does not exceed two and three-quarter inches in length, the median enlargement can be reached and efficiently treated through the perineum. If the form of the median enlargement be pedunculated or very salient, the suprapubic operation is preferable to the perineal. Upon the distensibility and capacity of the bladder the possibility of performing that operation after the modern method depends. The study of the altered anatomical conditions resulted in showing that in almost every case the median enlargement formed the chief obstacle to urination: that in two-thirds of the cases this portion can be reached successfully through the perineum; that in nearly one-third of the cases the great perineal distance, or the salient form of the median enlargement, made the suprapubic operation that of choice. In other words, that we are compelled to resort to one or another of these operations, according to the nature of the elements recounted above. The clinical evidence made the following showing: Of palliative operations by drainage there were twenty-four cases and twelve deaths (fifty per cent. mortality); of these, suprapubic puncture, with retained cannula, is the most dangerous, and perineal drainage the safest. Of the radical operations there were fifty-three cases, with sixteen per cent. mortality; of these, the perineal operations were the safest.

The author's personal contribution to the subject consisted in the report of two cases of the radical operation, the first a suprapubic prostatectomy in a person aged eighty, who died on the fourth day following operation of acute irritative urinary fever; the second, a case of perineal prostatotomy in a patient aged seventy-four, who made a perfect recovery, and, from being in a state of the utmost misery and danger, was entirely restored to health. The author also showed a perineal drainage-tube of his own device, to drain the bladder after these operations, or other similar ones, and also a galvano-cautery prostatectatome. In conclusion, he stated that, inasmuch as the anatomical investigation had shown that the perineal operation was perfectly practicable in two-thirds of all cases occurring in old people, and as it had also been shown to be clinically the safest that the action in any given case should be to open the perineal urethra and explore with the fingers—the surgeon should complete the operation by this route when possible, but when not, for the reasons already laid down, proceed either at once or later to the suprapubic operation, according to the condition of the patient.

Discussion: In answer to a question, the author said that the portions of prostate removed appeared usually hard and fibrous—sometimes, however, yielding, probably glandular.

THE PRESIDENT thought that a diagnosis as to the operation proper to the case could ordinarily be made without exploratory incision by the use of sounds and the finger in the rectum, to which the author gave assent.

DR. L. BOLTON BANGS, of New York, read a paper entitled

CLINICAL OBSERVATIONS OF DISEASES OF THE TESTICLE.

He reported three cases. The first case was an inflamed, undescended testicle, sent to the hospital for strangulated hernia. When the inflamed spermatic cord was incised, there was escape of pus. On the day following, patient had a distinctly purulent urethral discharge. Points raised were: (1) The novelty of this escape of pus from the cord, and (2) the relation of the urethritis to this condition. Did the orchitis precede the urethritis, or did the urethritis precede the orchitis, the former abating while the orchitis existed, as in ordinary orchitis associated with urethritis?

Second case, presented as a type of chronic inflammation of testicle due to prolonged irritation of the prostatic urethra. The testicle had all the characteristic appearances of a tubercular testicle, and castration was about to be performed, but the author objected, and the patient was relieved by the escape of a prostatic calculus. The symptoms all subsided, and the sinus closed spontaneously.

Third case was that of true tuberculosis of the testicle, complicated by traumatic hydrocele; an interesting clinical feature of the case being the rapidity of the tubercular process and in the large amount of fluid in the tunica vaginalis. A majority of cases of tubercular testicle are curable, but there is a rapidly developing form which is not.

DR. FRANK W. ROCKWELL, of Brooklyn, presented a case in which both testicles had been removed for a

PRIMARY CANCER OF THE EPIDIDYMIS

of the right, followed in three months by a similar affection of the remaining gland. No involvement of the testicle proper, nor return of the growth in side first affected. Diagnosis confirmed by microscopic examination, and the patient was still well at the expiration of nearly two years. The doctor had been able to find no other case on record where the epididymis had been primarily affected, and with the same clinical history, and believed the case unique.

DR. WILLIAM M. MASTIN, of Mobile, Ala., presented a paper on

THE HISTORY OF THE FILARIA SANGUINIS HOMINIS; ITS DISCOVERY IN THE UNITED STATES, AND ESPECIALLY THE RELATIONSHIP OF THE PARASITE TO CHYLOCELE OF THE TUNICA VAGINALIS TESTIS.

This was read by the Secretary, Dr. Taylor. The paper was elaborate and gave a very exhaustive *résumé* of all that has been published on the parasite, and will furnish a valuable source of information for those who may desire to study the subject.

DR. ALEXANDER W. STEIN, of New York, read a paper on

SOME POINTS IN THE DIFFERENTIAL DIAGNOSIS OF BLADDER AND KIDNEY AFFECTIONS,

with demonstrations of cystoscope and other instruments.

The author referred to the importance of recognizing irritation in other parts as expressed in bladder symptoms. Dilatation of the vesical neck will often remove cystic symptoms. Again, the irritation may be beyond the bladder. Stringy, purulent urine may come from the renal pelves. He illustrated this point by a case presenting all the symptoms of cystitis, in which the autopsy showed only a sarcoma of one kidney. The use of the cystoscope in bladder disease was able to render great aid in arriving at a correct diagnosis, revealing the condition of the mucous membrane, presence of morbid growths and their nature, calculi, etc. In kidney disease, lumbar incision affords an important means of differentiation in surgical cases. The difficulties in catheterization of the ureters render this aid to diagnosis of little practical value. The same may be said of the use of other means designed for aiding diagnosis by various instrumental manipulations of the ureters, such as to seize one of them by forceps, etc.

Professor Annandale, of Scotland, emphasized the importance of cystoscopy. He referred, as illustration, to a case of obscure hæmaturia, in which the autopsy showed that it was from a pelvic sarcoma. Here the cystoscope would have disclosed the blood flowing from the corresponding ureter, and would have indicated the location of the disease and have suggested the proper procedure as to treatment.

The President remarked that the effective use of the cystoscope required educated skill. He related a case of pus in the urine in which Freund, by catheterization of the ureters in a woman, diagnosed disease of one kidney, and the other kidney as healthy. He operated on this, and removed the diseased kidney. He discovered, by examination of the supposed healthy kidney, by manipulation through the abdominal incision by which the operation was performed, he thought, at the time, evidence of disease. After the operation the urine became clear of pus, but the patient soon developed uræmic symptoms and died.

Surgeon-Major Keegan, of Indore, Central India (by invitation), presented a paper entitled

LITHOLAPAXY IN MALE CHILDREN.

The author remarked that nowhere had the operation of litholapaxy been more favorably received and made use of than in the British colonies and dependencies. Recently, out of 35 male children under his charge for vesical calculus, 33 were removed by litholapaxy; the mortality was $3\frac{5}{10}$. Very large and hard stones in boys may thus be removed. Fully fenestrated lithotrites are used by the author in operating on boys—No. 6 (2) to No. 10. None of his cases had returned with recurrence of stone. In India litholapaxy is likely to become the conventional operation in ordinary cases of small stone in boys, in the author's opinion.

Dr. Abner Post, of Boston, reported an operation for

ENLARGED PROSTATE AT THE AGE OF FORTY-TWO.

The patient's symptoms had existed since he was twenty-one, and appeared to date from an injury by the caving in of an embankment, but were possibly of longer duration. The patient was unable to pass urine except he assisted himself by inserting the finger in the anus and pressing along the course of the urethra. No instrument could be passed into the bladder. On opening the urethra in the perineum neither instrument nor finger could enter the bladder until a section of the prostate had been made with the knife. The prostate was of stony hardness.

Dr. Post did not believe the enlargement to be of the same character as the ordinary senile hypertrophy. The section of the prostate was successful in re-establishing the power of micturition.

Dr. Fessenden N. Otis, of New York, demonstrated

A PERFECTED EVACUATOR AND AN IMPROVEMENT IN THE METHOD OF REMOVAL OF DÉBRIS FROM THE BLADDER.

The instrument is a modification of his previous evacuator. The modificators are the removal of all stopcocks, the removal of tubing between bulb and globe, and between globe and evacuating tube; thus making the instrument more compact, and the distance from the bladder to the receiver the shortest possible. Introduction of hard rubber in place of metal gives the utmost lightness. The author claims that this presents the following advantages over all other instruments now in use: 1. Perfect trapping of all fragments, without the use of any form of valves, perforated tubes or strainers. 2. The shortest possible route of fragments from the bladder to the receiver. 3. Absence of all stop-cocks between the bladder and the receiver. 4. The ease of filling and perfect control of the amount of water in the bladder during evacuation. 5. Lightness, compactness, power, and facility of manipulation. 6. The fragments being visible from the moment of leaving the tube until removed from the receiver, it can be seen that they do not return to the bladder. 7. Comparatively small cost; fewer joints liable to come loose.

AMERICAN NEUROLOGICAL ASSOCIATION.

Wednesday, September 19th—Second Day.

Dr. F. X. Dercum, of Philadelphia, presented a paper on

A SUBCUTANEOUS CONNECTIVE-TISSUE DYSTROPHY OF THE ARMS AND BACK, ASSOCIATED WITH SYMPTOMS RESEMBLING MYXŒDEMA,

with photographs and microscopic sections illustrating the case. There was a mucous condition of the subdermal tissue, and connective-tissue changes in the nerves and ganglia of the parts. There was some anæsthesia. The thyroid gland could not be felt. There were not the slowness of speech, thought, and movement, and the mental condition characteristic of true myxœdema.

Dr. C. K. Mills stated that he had seen and examined this patient frequently, and related facts in a somewhat similar case, where the face was involved. This patient died suddenly, and no autopsy could be obtained.

Dr. W. A. Hammond said that although he was struck by the analogy between the author's case and myxœdema it was not that disease. It lacked the mental derangement. He referred to his monograph on two cases of this disorder. In one of them half a minute was required to elicit an answer to the most trivial question. Changes in the thyroid gland are necessary to a diagnosis of this disease.

Dr. Putnam thought that cases might present pathological or clinical differences, and that this might be valuable as an example of a transition case or peculiar form of myxœdema.

Dr. Dercum, in closing the discussion, said that Horsley had examined the specimens this morning and thought the case transitional in character, but not true myxœdema. Recent cases have been reported where mental symptoms were not marked. His own had presented some irritability. The thyroid is not usually enlarged but wanting.

Dr. G. W. Jacoby, of New York, then contributed a report of a case of

SUBACUTE PROGRESSIVE POLYMYOSITIS.

The author reviewed the inflammatory muscular disorders. There are only three cases recorded precisely similar to his. His own presented clinical symptoms of progressive inflammation of the muscles, beginning in the lower extremities and successively involving nearly all the muscles of the body; it was characterized by pain, swelling, inhibition of function, with ultimate atrophy of certain groups, ending fatally in two and one-half years through involvement of the respiratory muscles. There was, microscopically, a subacute parenchymatous myositis. He concluded that it was a case of acute primary myopathy, closely allied to the chronic forms known as chronic progressive muscular atrophy.

Dr. B. Sachs, of New York, then read a paper on

MUSCULAR DYSTROPHIES.

The following is a brief summary of his comprehensive monograph: Progressive muscular atrophy, type Aran-Duchenne, is due to spinal-cord disease. The peroneal type bears a close resemblance to this form, and may possibly have the same pathology. Duchenne's form might be termed the hand type, and the peroneal the leg type. Pseudo-hypertrophy is not of spinal origin, and lipomatosis is a mere incident in its course, associated with wide-spread atrophy in various parts of the body. There is a close relation between pseudo-hypertrophy and Erb's juvenile form of progressive muscular atrophy, but no absolute identity. All forms of primary myopathy are occasionally hereditary; hence, hereditary muscular atrophy does not deserve the rank of a separate clinical entity. The type Landouzy and Déjérine is closely related to Erb's form, the involvement of the facial muscles not sufficing for wide clinical differentiation. Pseudo-hypertrophy and Erb's form should be regarded as the two representative forms of primary progressive dystrophies. The latter are distinguished from the spinal progressive dystrophies by the occurrence of true or false hypertrophy, the absence of the reaction of degeneration, and the absence of fibrillar contractions. He would classify muscular atrophies as follows: 1. Amyotrophia spinalis progressive. *a.* Hand type; *b.* Leg type=peroneal form. 2. Primary progressive dystrophies. *a.* Pseudo-hypertrophy; *b.* Erb's form. The papers of Drs. Jacoby and Sachs were discussed together.

Dr. Knapp agreed with Dr. Sachs that progressive muscular atrophy is spinal in origin, that the peroneal type is a form of that, and that pseudo-hypertrophy is not spinal.

Dr. Jacoby thought that it was difficult in some cases to draw a distinct line between the spinal and muscular types. The presence or absence of hypertrophic fibres is usually sufficient for a differential diagnosis between the two, but not always. He believed that in most of these cases there is some embryonal malformation, rendering the muscles liable to molecular changes in later life.

Dr. L. C. Gray was of the opinion that exact inferences cannot be drawn from cases now on record, because they are so contradictory. Pseudo-hypertrophy is probably of peripheral origin, yet there are cases where legitimate doubts may be entertained regarding this, for autopsies by excellent pathologists have revealed spinal lesions.

Dr. William A. Hammond agreed with Drs. Sachs and Jacoby upon their general deductions. He referred to the chapter on pseudo-hypertrophy in his book, which Dr. Sachs had criticised, saying that it was first written eighteen years ago, and rewritten for the last edition four years ago. Even in this short period much had been learned concerning these diseases, and he was ready at any time to alter his convictions when sufficient arguments were presented. It is easier to be critical than to be an explorer. It is not wise to make decided statements upon the still uncertain data in this disease.

Dr. Walton detailed a case of pseudo-hypertrophy with a hereditary history.

Dr. Putnam had prepared the report of a case of hereditary atrophy, and showed drawings and microscopic specimens illustrating the disease. One specimen was from the muscle of a man with progressive muscular atrophy, who had travelled about the country as "the living skeleton."

Dr. Sachs, in closing the discussion, stated that he claimed only to have reviewed the literature of the subject thoroughly, and was compelled to do so critically. Hence he had been obliged to differ to a slight degree from Drs. Hammond and Gray's opinions.

The meeting then went into executive session, and elected Dr. David Inglis, of Detroit, a member.

Dr. James H. Lloyd and Dr. John B. Deaver together contributed reports upon

A CASE OF FOCAL EPILEPSY SUCCESSFULLY TREATED BY TREPHINING AND EXCISION OF THE MOTOR CENTRE.

The operation had been performed in June last, and there had been no epileptic attack since.

Dr. David Ferrier, of London, thought it a little too early to consider the case cured. In some of his own cases of focal and Jacksonian epilepsy, treated by operation, he had been disappointed by the recurrence of the spasms. One case was very similar to this. A spiculum of bone wss supposed to be the cause, and Lister trephined, but did not find anything. The fits continued, and one year later the operation was repeated by Horsley, but without success. The sooner cases are operated upon after the injury the better, as in chronic cases the danger of recurrence is so much greater. From the paresis present, there was probably some organic lesion in Dr. Lloyd's case, although it was not discoverable. One case of his had three thousand fits in fourteen days. Horsley operated upon this, and there has been no recurrence as yet. Such cases as Dr. Lloyd's were very interesting in the light of physiological experiment, showing the similar reactions to faradism of the motor centres in both man and monkey.

Mr. Victor Horsley, of London, mentioned a case of his where epilepsy recurred two years after operation, and another where there was recovery with mental equilibration, not present before operation. All of these cases should be operated upon as early as possible. He was gratified that the use of faradism in diagnosis had been adopted in this country. In testing sensibility we must remember that there is a sense of movement and a sense of a part having been moved, and the two must be distinguished. Dr. Deaver's cutting the flat of the scalp with convexity downward was inadvisable. He had tried it, but found it did harm to cut the temporal artery. Drainage would be equally good and the nutrition of the part better, if the convexity of the flat were backward. He was glad to see the successful use of cocaine in this case to contract the arterioles in the membranes. Recently, Prof. Schäfer and himself had decided by experiment that intermittent irrigation while operating would be more liable to lead to bad results than if continuous, and he consequently uses the antiseptic spray as a means of constant irrigation.

Dr. W. W. Keene stated that he did not use the spray in his cases, and saw no reason for its employment. The washing with sponges was the only irrigating process he required.

Dr. Gray was glad to hear Dr. Ferrier and Mr. Horsley say that cases trephined for epilepsy should not be pronounced finally cured until five years had elapsed. He related a case of his own, with intra-cranial syphilis, trephined by a surgical friend, who unfortunately was not a believer in antiseptic surgical methods. The patient died a few days subsequently of suppurative encephalitis.

Dr. C. L. Dana inquired of Dr. Lloyd if there was absolutely no anæsthesia in his case. Dr. Lloyd said there was very slight blunting when tested by the two points of an æsthesiometer. But Dr. Dana believed that, from the recorded history of the case, it would be fair to conclude that there was some loss of sensibility. The sensory aura was certainly lost, as it disappeared after the operation.

Dr. Mills said he had studied the case of Dr. Lloyd both before and after the operation, and would say that there was absolutely no loss of tactile sensibility.

Mr. Horsley remarked that the best method of testing the sense of touch was to have the patient, with blindfolded eyes, locate the point of touching with the opposite hand. When there is recovery from tactile anæsthesia it progresses outwardly to the periphery.

Hence in the fingers, for instance, the first phalanges recover feeling, then the second, and the tips last.

Dr. Seguin mentioned, in connection with the case recently reported by himself and Dr. Weir, that since last year the epilepsy has recurred and there is more paresis. In this case there is unquestionable tactile anæsthesia of the face, arm, and fingers of the side affected. The temperature and muscular senses are normal.

Dr. Ferrier asked if there was anæsthesia in the leg, where the tumor was, and what was its size.

Dr. Seguin said that sensation was normal in the leg. The tumor was situated in the face and arm centres, and was eighteen to twenty millimetres in diameter.

Dr. Lloyd closed the discussion by stating that he had, a few hours before, received the pathological report in his case, upon the pieces of cortex removed. Dr. Smith, of Philadelphia, had found some evidence of degeneration in the pyramidal cells.

Dr. James J. Putnam, of Boston, then read a paper entitled

OBSERVATIONS AND EXPERIMENTS RESPECTING THE PATHOLOGY OF NEURITIS,

richly illustrated by drawings and numerous microscopic specimens. The author related the history of an interesting case of multiple neuritis.

Dr. S. G. Webber mentioned cases of his own somewhat similar. He had experimented upon rabbits and guinea-pigs by exciting neuritis. He found that most changes in the early stages of neuritis were near the constrictions of Ranvier. On one occasion, when there seemed to be an epidemic of multiple neuritis in Boston, there was at the same time a similar disease with paralysis, etc., among horses in the city; but he had not examined the nerves in any.

Dr. Pye-Smith, of Guy's Hospital, London, asked whether gout had been observed in this country as a cause of neuritis. He had had such a case where there was no alcoholism to account for it. He desired to know if the enigmatical disorder known as Landry's paralysis was as rare in this country as in England.

Dr. Van Bibber related the history of a case of his presenting symptoms such as Dr. Putnam had mentioned.

Dr. Dana, answering Dr. Smith, said he had seen cases of localized neuritis due to gout quite frequently, and also two cases of multiple neuritis which he ascribed to acute rheumatism.

Dr. Putnam said that gout was a rare disease in America, but is well known to cause sciatica and other forms of local neuritis. Neuritis attends rheumatism at times. Landry's paralysis is exceedingly rare here.

Dr. E. C. Seguin exhibited for Dr. J. C. Shaw, of Brooklyn, some microscopic specimens of peripheral nerves in locomotor ataxia, showing neuritis.

Dr. Burt G. Wilder's paper on "The Relation of the Thalamus to the Paracœle (Lateral Ventricle)" was read by title in the absence of its author.

The officers of the Association for the ensuing year were then elected, as follows: *President*, Dr. E. C. Seguin, of New York; *Vice-Presidents*, Dr. C. L. Dana, of New York, and Dr. Philip Zenner, of Cincinnati; *Secretary and Treasurer*, Dr. G. M. Hammond, of New York; *Members of the Council*, Dr. J. H. Lloyd, of Philadelphia, and Dr. M. Allen Starr, of New York.

Is the World Satisfied with the Medical Profession? asks Dr. Cocke in Daniels' *Texas Medical Journal*, and he apparently believes that it is not. As one means of satisfying the world he urges his Texas colleagues to "unite as one man, and at the Galveston meeting make it known, that we will support no man, from senator down to the private secretary of the mayor, unless he declare for reform and high tariff for medicine, and low tariff for everything else."

AMERICAN OPHTHALMOLOGICAL SOCIETY.

Special Meeting, September 19, 1888.

Morning Session.

Dr. Henry W. Williams, of Boston, President Pro Tem.

Dr. David Webster, of New York, read a paper upon

SOME TENOTOMIES FOR THE CORRECTION OF HETEROPHORIA, WITH RESULTS.

He reported forty cases; twenty-five had been operated on but once, in sixteen a second operation was done, and three had previously been operated on by others, making a total of sixty tenotomies. The operations had been done since the beginning of July, 1886. The method was that described by Dr. G. T. Stevens, except that the tendon was always entirely divided. A slight over-correction was usually aimed at and attained. In three cases a slight reduction of the effect was necessary. In a single case he regretted having operated. All operations were done under cocaine, and the eyes tested from time to time, to determine when sufficient effect had been produced.

Among these cases there were four epileptics, none of whom were cured; in one there was a temporary suspension of the fits, and in another they were thought to have been favorably modified. There were two cases of chorea, both of which seemed favorably influenced. In three hysterical males remarkably good results were obtained. Most of the operations were done for headache and asthenopia. The writer had reached five conclusions, viz.: That no person should have a tenotomy done for heterophoria, without inconvenience probably due it; very slight degrees may cause trouble, and should be attended to. All other methods should be tried before tenotomy. The operation should be performed under cocaine, and the eyes from time to time tested to guard against over-correction; and that in properly selected cases, the results are quite as good as are obtained by most other surgical procedures.

Dr. Samuel Theobald, of Baltimore, read a paper entitled

IS ASTIGMATISM A FACTOR IN THE CAUSATION OF GLAUCOMA?

He was convinced that the direction of the meridians of greatest and least refraction determines to a marked degree the amount of asthenopia, etc., attending this form of ametropia. When the meridian of lowest refraction is vertical or nearly so, the asthenopia, headache, and likelihood of pathological changes in the eye are greater than when it is horizontal or nearly so. The slightest degree of astigmatism of this character almost always gives rise to trouble, and if it amounts to not more than 0.25 D. requires to be corrected. The non-asthenopic astigmatic eyes are rarely of this sort, but cases in which the meridian of least refraction approaches the horizontal. Astigmatism in which the meridian of least refraction approaches the vertical are less common, and must be regarded as the wider departure from emmetropia. Because of a more persistent effort of the ciliary muscle to correct it, this form is more difficult to detect; and it will not all be revealed at a first examination, even by the aid of a mydriatic. The writer found this variety of astigmatism in almost every instance associated with glaucoma, so that he was disposed to regard the association as not accidental. Hyperæmia of the ciliary muscle is a common result of astigmatism, especially of this form. This would induce an undue flow of fluid into the vitreous, and if the anterior drainage apparatus happened to be inadequate, a glaucomatous condition would result. Cases of glaucoma with astigmatism of this form, and of astigmatism, mostly of this form with threatened glaucoma, were related.

Dr. Peter A. Callan, of New York, read a paper on the

TREATMENT OF ULCERS OF THE CORNEA.

The ulcers occurring in young persons and children are really phlyctenulæ of the cornea, or neglect of lid friction causing absorption gives rise to an ulcer. The treatment is yellow oxide of mercury salve (two to ten per cent.) placed between the lids once daily; atropia and cocaine if necessary; tonics; open-air exercise; regulation of diet; airy sleeping quarters; smoke-glasses; avoidance of dark room or bandages. The ulcers due to conjunctivitis need no special treatment other than that for the disease causing them. In gonorrhæal ophthalmia, ophthalmia neonatorum, or granular lids, we always redouble our efforts when the cornea is likely to become involved; cutting the canthus, applying leeches or ice, etc. He referred especially to ulcers occurring without apparent cause, due to some constitutional trouble, malaria, syphilis, etc. For these give the remedy for the constitutional ailment, and locally cocainize the eye thoroughly, and clean the ulcer with a piece of absorbent cotton wrapped on a holder, and with the same as an applicator swab the ulcer, leaving no part of it untouched, with a two-per-cent. solution of silver nitrate. This may have to be repeated two or three times in the course of as many days. Bathe the eye with hot water, (120° to 130° F.) three times daily for a half-hour. If much corneal irritation exists, bathe with boric-acid solution, and use atropine and cocaine after each bathing. The point is to get a clean wound; and silver nitrate, besides stimulating repair, is a safer, better means of doing this than any other known to the writer.

Afternoon Session.

Dr. Edward Jackson read a paper entitled

MERIDIONAL ASTIGMATISM.

By this name was designated the defect of the eye which caused a difference between the refraction of the eye at the centre of the pupil, and the refraction at the pupillary margin. It is to be detected and studied by the shadow-test, with which it causes an erect image and an inverted image of the light area to be seen in the pupil at the same time; one at the centre of the pupil the other at its margin. His deductions of practical interest were that it was the lower degrees of the defect that were most likely to interfere with vision; that it was a cause of different refraction in the eye with a contracted pupil from that of the same eye under a mydriatic; and that it was especially apt to cause symptoms of asthenopia in those whose complaints were chiefly connected with near work or exposure to a bright light.

The committee, composed of Drs. Edward Jackson, Henry D. Noyes, and Swan M. Burnett, appointed to consider the

PROPOSITION TO DESIGNATE PRISMS ACCORDING TO THEIR REFRACTIVE POWER,

recommended the indorsement of the following propositions:

1. Prisms ought to be designated by the number of degrees of "minimum deviation" they produce.
2. Where intervals of less than one degree are desired, half-degrees and quarter-degrees should be used.
3. To indicate that degrees of deviation are meant, the letter "d." shall be added. Thus, "prism 2°d." will indicate a prism that produces a minimum deviation of two degrees.

Dr. J. Oscroft Tansley, of New York, exhibited and explained

A NEW INSTRUMENT FOR DEMONSTRATING REFRACTION,

consisting of a box with glass sides, with a magic-lantern attached, and arranged for the adjustment of various lenses. The box was to be filled with smoke, in which the courses of the rays from the lantern would be quite plainly visible.

Dr. W. F. Mittendorf, of New York, reported three cases of

ACUTE COCAINE CONJUNCTIVITIS.

It was to be expected that idiosyncrasy, such as constitutes a bar to the use in certain cases of other drugs, would be found to exist with reference to cocaine. These cases occurred after the use of a four per cent. solution of the drug, and were characterized by swollen, shiny lids, and a profuse acrid discharge. Two of the cases occurred in elderly women, and the third in a man. In one of the women, after relief had been obtained by cessation of the use of the drug, a renewal of its use was promptly followed by a renewal of the trouble. In the man three separate attacks were caused at different times by different applications of the drug. It is likely that the condition is due to a paralyzing effect of the drug on the terminal sympathetic nerve filaments.

Dr. S. M. Burnett, of Washington, exhibited some

APPARATUS FOR DIAGNOSIS OF REFRACTION.

This consisted of a disk of lenses to be used in applying the shadow-test, arranged to be fixed to the wall and adjustable to any height, and readily used for either eye, or swung out of the way when not in use.

Dr. Carl Koller, of New York, read by invitation a paper on

BLEPHAROSPASM.

Although this is only a symptom, it is an important one. Cases might be divided under three heads; viz., the neurotic, the hysterical, and those in which it was a reflex of irritation of the nerve-endings of the cornea and conjunctiva. The latter included the cases of phlyctenular disease. Cocaine, from which he had at first hoped much, had proved useless, exerting but a slight influence when very freely applied. An essential factor in the continuance of the spasm is a fissure that forms at one canthus, usually the outer, making a condition resembling fissure of the anus. The cure here may be effected by division of the muscle, but this is not usually necessary. Treatment of the conjunctival condition, cauterization of the fissure with copper sulphate, and the application of the ointment of yellow oxide of mercury are commonly sufficient.

Dr. R. H. Derby, of New York, reported a case of

MONOCULAR OPTIC NEURITIS,

in which the swelling of the papilla at one time reached seven dioptrics, and light perception was lost. Under large doses of potassium iodide, and mercurial inunctions, the swelling had been greatly reduced, and vision had returned and improved to seven-tenths.

Dr. O. D. Pomeroy, of New York, reported five cases of

REMOVAL OF THE DISLOCATED CRYSTALLINE LENS WITH THE BIDENT.

This instrument, proposed by the late C. R. Agnew, had proved a very satisfactory aid in the hands of the few who had tried it. In all these cases good vision was obtained. Care must be taken not to press the lens too far forward with the bident, and it must be extracted with a scoop or sharp hook.

Pneumococcus in the Saliva.—Dr. Netter has examined the saliva of a number of patients at varying intervals of a few days to twelve years after an attack of pneumonia, and has found Fraenkel's pneumococcus present in sixty per cent. of the cases. The virulence of the micro organism there found seems to increase, within certain limits, in proportion to the length of time that has elapsed since recovery from the disease.

AMERICAN DERMATOLOGICAL SOCIETY.

Wednesday, September 19th—Second Day.

Dr. J. E. Graham, of Toronto, Canada, read a paper upon

A REPORT OF THREE CASES OF DERMATITIS HERPETIFORMIS.

The first two cases were males and the third was a female who died. As a young woman the latter case had suffered from eruptions of a vesicular and bullous character. The day after the birth of her second child the patient developed a bullous eruption at the corner of each eye, followed by lesions upon the face, the size of a ten-cent piece and a quarter, which extended from their borders. Death took place a month after the patient was first seen.

Following this paper, **Dr. H. W. Stelwagon**, of Philadelphia, Pa., read upon

DERMATITIS HERPETIFORMIS, WITH NOTES OF THREE CASES.

But three cases are recorded out of a total of eight thousand, two of which may be said to typically represent the vesicular variety of the disease, the third being of multiform nature, at one time simulating pemphigus, at another erythema multiforme, and at still another herpes iris.

Dr. Hyde, of Chicago, said that we must separate impetigo herpetiformis and pemphigus foliaceus from the cases of dermatitis herpetiformis described in the papers. A long history of eruptive outbreaks is necessary for a diagnosis according to Duhring. He related one case in which there was a history of many returns of an eruption of bullæ-vesicles and pustules, in which extensive exfoliation of the skin of the back had taken place, and the continuous water-bath had been used.

Dr. Bulkley referred to Dr. Atkinson's address, and agreed with him that we must look in various directions for the pathological basis for these eruptions. He had shown a case of typical dermatitis herpetiformis at the New York Dermatological Society. The eruption had lasted for a year, and the patient had died in six months of diffuse internal sarcoma. A second case like those mentioned in the papers had died a month ago of acute congestion of the brain. He would class one of Dr. Graham's cases as a pemphigus. Dr. Stelwagon's first case is typical, and the only phase to which he is willing to accord the name dermatitis herpetiformis, and protests against impetigo herpetiformis being entered under this term.

Dr. Fox said he had seen and treated Dr. Stelwagon's second case, and it had shaken his faith in the identity of these cases. It illustrated how a disease may pass through different phases, and have the features of one disease at one time and of a different disease at another. When first seen this case was erythematous without the bullæ or vesicles which had previously been present.

Dr. Heitzmann said that twelve years ago, he had described a case of impetigo in a non-pregnant woman, but which turned out to be a pemphigus in its later stages. It had been considered a disease exclusively belonging to the puerperal state; Kaposi had since, however, described a case in a man. When Duhring included it in his disease he had been shaky about the correctness of it. He had seen a case with his son which had been called pemphigus, but which they agreed was a true case of Duhring's dermatitis herpetiformis; but if impetigo herpetiformis was included in the term he must disagree.

Dr. Shirwell had seen several cases of a typical nature and had found diabetes present. Under anti-diabetic treatment the eruption had improved, and he thought examination of the urine should not be overlooked.

Dr. P. A. Morrow then read a paper on

THE RELATIONS OF PAPILLOMA TO SYPHILIS AND TUBERCULOSIS OF THE SKIN, WITH REPORT OF A CASE.

Papilloma is a term which has been applied to a variety of papillary growths possessing characteristics in common, but originating under widely differing etiological conditions. Frambœsia may be taken as the clinical type of a variety of conditions possessing similar histological characters. The proliferations are more or less allied to the giant granulations of wounds and ulcers, and it is often impossible to determine whether the process be primary or secondary. The case reported presents a rare and unusual development of the lesions. The patient, a male, aged thirty, had enjoyed good health until some two years ago, when his arm was amputated on account of some disease of the bone. When admitted to Charity Hospital an exuberant growth of papillary excrescences of cauliflower form covered the entire nose, both cheeks, right upper lid, and upper lip. They were of soft consistence, becoming dry and hard when exposed to the air, extremely vascular and of deep raw-flesh color. Itching and pain were marked. The lesions resembled condylomata, and corresponded to a case described by Dr. De Amicis as frambœsia condylomatous syphiloderm. He was first treated with mercury internally, ointments, and a powder containing salicylic acid, gr. x., boracic acid, gr. xx., and calomel, ʒ j., under which improvement took place at first, but the growth extended and a variety of different local applications were employed without any permanent benefit. The disease, it was learned subsequent to this time, had begun as a verrucose tubercle on the side of the nose about the size of a pea, about four months before his arm was amputated, and some months later began to increase rapidly in size and extent. The diagnosis of syphilis was excluded by the character of the initial symptoms, the sluggish mode of development, the nature of the inflammatory element, the absence of other symptoms, and the failure of anti-syphilitic treatment.

Lupus verrucosus and tuberculosis verrucosa cutis were suggested. Aside from the evidence of bacteriology it must be admitted that there is strong presumptive proof of a close connection between lupus and tuberculosis. The statistics quoted by Dr. G. T. Elliot, in a recent paper on tuberculosis verrucosa cutis are very significant. They show that a large percentage of lupus patients are tuberculous, or become so. Again, Rhiel and Paltauf admit the resemblance between a form of cutaneous tuberculosis and verruca necrogenica, the origin of which is generally held to be the accidental inoculation of tuberculous material. The identity is also probable from the demonstrated presence of tubercle bacilli in both forms. Lupus verrucosus and tuberculosis verrucosa cutis present many analogies, and do not differ materially in their typical papillomatous features, and an absence of ulceration is common to both. The author is inclined to believe that the case he reports is one of cutaneous tuberculosis. Dr. Elliot examined sections of the growth and found the tubercle bacilli. Furthermore the genesis, evolution, etc., support this view, and it is probable that the disease for which the arm was amputated was tubercular osteitis. Statistics show that primary tuberculosis is quite common in the bones of the forearm and metacarpus. The nose probably became affected by auto-inoculation, and the papillomatous proliferations have developed without pre-existing ulceration, advancing at the periphery, but fresh foci have also developed at distant points. After the diagnosis of tuberculosis was made, injections of iodoform in oil of vaseline were given, and as the patient objects to operation, treatment is directed chiefly to relief of subjective sensations.

Dr. Fox said he had repeatedly seen tubercular syphilides modified by frambœsia or papilloma, but he could not remember to have ever noted the modifying effects of syphilis upon ordinary skin diseases, about which we hear so much.

Dr. Bronson said he had treated the case which was the subject of the paper, and had regarded it as most likely due to syphilis.

Dr. Sherwell took issue with Dr. Fox in regard to the influences of syphilis upon eczema and other skin diseases.

Dr. Heitzmann regarded the tubercle bacillus as settling the nature of the growth in this case, whether it be called lupus or tuberculosis. He had had an inoculated local tuberculosis upon his own finger (verruca necrogenica). He thought there were few dermatologists who did not admit the identity of lupus and tuberculosis. The papillary tumor is not characteristic of syphilis, but, on the contrary, verruca accuminata are non-syphilitic, while syphilitic warty growths are flat.

Dr. Bulkley said he was inclined to accept the identity of lupus and tuberculosis of the skin.

Dr. Robinson said the question of identity in lupus and tuberculosis of the lung was not proven positively. The objection is that lupus had not been produced by inoculation of bacilli.

Dr. H. W. Stelwagon, of Philadelphia, read a paper on

MOLLUSCUM CONTAGIOSUM,

in which he reviewed the opinions as to the contagiousness of the disease which are held here and abroad. He referred to a contribution from Dr. Allen, which he said appeared to prove that the disease has contagious properties, and his own observations, which cover no less than thirty-two cases, have led the author to change his own views on the subject, although he was not able to inoculate the disease.

Dr. Morrow said he had been struck, many years ago, with the fact that molluscum occurred now and then in several children in the same family, but had never been able to trace the contagion. Analogies have been noted between this disease and warts. The cases reported surely point to contagion, still he has held the opposite view, and regards it still a mooted question.

Dr. Sherwell said he had found it an extreme rarity. He saw a number of cases in an institution, a number of years ago, which had altered his views as to its non-contagiousness.

Dr. Robinson believed in its contagiousness, but had never been able to trace its contagion. He had only seen a few cases out of many thousand children examined; while other observers, as Dr. Allen, who probably had not examined so many children, had reported about fifty cases seen at one time. He believes it in reality a parasitic disease.

Dr. Fox said he had made repeated inoculations, but they were all unsuccessful. So far as he was aware, the only successful result was that of Retzius. It was generally found among the poor in asylums, but he had found it, too, in perfectly healthy, well-cared-for children. He had reported twenty-five cases at the first meeting of this Association. Dirt and dampness may contribute toward its occurrence. He had spoken several years ago of the coexistence of warts and molluscum. He thinks them both contagious, and venereal warts are surely so.

Dr. Allen, on invitation of the Chair, said he had recently seen in the Baretta Museum of the St. Louis Hospital, in Paris, a wax model showing a perfectly typical lesion of molluscum contagiosum, which had been produced upon the arm of an infant by inoculation, and it seemed to him that this, together with the successful inoculation by Retzius, was sufficient to prove that the disease may be transmitted by inoculation.

In closing, **Dr. Stelwagon** said he had noted no connection between common warts and molluscum.

Dr. A. R. Robinson read a paper upon the same subject, entitled

THE QUESTION OF RELATIONSHIP BETWEEN LICHEN RUBER (HEBRA) AND LICHEN PLANUS (WILSON).

In the opinion of this writer the presence of dark-red, round, or irregularly shaped flat papules which show no tendency to become vesicles, justify the diagnosis of a lichenoid eruption, but not of the disease lichen planus. For that diagnosis the clinical symptoms must correspond to those of undoubted cases. In some of the cases in which lichen planus has been described as existing in connection with lichen ruber of Hebra, the lesions did not correspond as regards number, situation, grouping, etc., with those of ordinary lichen planus, and consequently the writer is not prepared to accept the diagnosis. Lichen planus may be present years or months without producing any marasmus, or show a tendency to attack the face, hair, or nails, but these parts are not absolutely exempt. All recent observers seem to regard the lesions as inflammatory in origin and not the result of a parakeratosis; but whether the changes depend upon organisms or a neuritis is a subject for study.

Arsenic is not a suitable remedy. Alkalies benefit some cases. If the diseases be similar etiologically, and arsenic be the drug for lichen ruber, the severer disease, then it surely should control the lesions of lichen planus.

According to Hebra's first description of lichen ruber the eruption consists of millet-sized, isolated, conical, bright-red or brown-red, firm papules situated around hair follicles, and covered on the apex with fine, adherent, dry, white scales; not arranged in groups, extending, new lesions continually forming. When papules coalesce the eruption appears as a red infiltrated patch covered with scales, and having a dry, rough, uneven surface. At the periphery characteristic papules are always present. A number of histories of cases reported by Unna as lichen ruber are quoted to show that from the description they do not resemble Hebra's disease excepting in the form of lesion. If such cases as Unna describes are examples of lichen ruber, we are then all familiar with the disease here, for such cases are not rare, and if left untreated do not assume a dangerous form. In lichen simplex the lesions resemble closely lichen ruber, and care in diagnosis is very evident.

In treating lichen ruber arsenic seems to act with certainty, provided the proper dose can be borne, and seems to be the only beneficial remedy.

The author concludes that from the study of the symptoms, lesions, histology, and prognosis there is absolutely no resemblance between the two forms of eruption. Admitting these differences, as it seems to the author we must, two different diseases must be admitted, unless it can be shown that the one form can change to the other, or that there is a tendency to an association of the two forms upon the same person, or that recurrences show variableness as to form.

The whole symptoms and course must enter into the formation of a diagnosis, and must not depend upon the lesion alone.

AMERICAN ORTHOPEDIC ASSOCIATION.

Wednesday, September 19th—Second Day.

Dr. Royal Whitman, of Boston, read a paper entitled

OBSERVATIONS ON SEVENTY-FIVE CASES OF FLAT-FOOT, WITH PARTICULAR REFERENCE TO TREATMENT.

He said: Clinically flat-foot is an affection, which, in the majority of cases occurs independent of local or constitutional disease. The direct cause is overweight or overwork for feet subjected to mechanical disadvantages.

These are, first, the common habit of turning out the toes in standing and walking, an attitude which brings an increased and continual strain on the weakest part of the foot; second, weakness of muscles from disease or deformities caused by improper shoes. Flat-foot, being essentially a dislocation, should be treated as other dislocations, by reposition and retention in the normal position until by exercise and avoidance of faulty position the muscles may regain their normal strength. In ordinary cases such retention can only be accomplished by some form of mechanical support. A brace should be constructed on principles somewhat as follows: It should be elastic, light, and comfortable; should fit the foot perfectly, and should not interfere with its normal movements or the action of its muscles. A steel brace designed on these principles was shown. In conclusion, it would seem that in many instances flat-foot might be prevented by teaching children that the proper attitude for the feet was with little or no divergence of the toes, an attitude which necessitated muscular activity in standing and walking; and, further, by avoiding improper shoes. The correct shoe should have a sole of moderate thickness approximating the shape of the Greek sandal; in other words, wide enough to support the foot and allow the toes to assume the proper position. The paper was illustrated by charts and diagrams, and was discussed by Drs. Taylor, Gibney, Lee, Vance, Ridlon, Moore, and Phelps.

Dr. De Forest Willard, of Philadelphia, read a paper on

OSTEOTOMY FOR ANTERIOR TIBIAL CURVES.

Rickets, although a constitutional disease, dependent upon mal-assimilation and mal-nutrition, yet exhibits its worst phases in deformities of the bones. The deformities are due to the relative preponderance of organic tissues in the bones, and the failure of the formative cartilage cells to produce true osseous cells. During this stage of softening many portions of the skeleton become disturbed, and when earthy salts are again deposited sclerosis results, and the faulty portions are permanently fixed. Anterior tibial curves are among the most frequent of these distortions.

Treatment.—1. Manual straightening and the employment of suitable apparatus. This may be successful in young children, with the bones still springy, but in all other cases it will utterly fail, and time and money will be wasted. Braces are useful in laterally bowed legs, but not in anterior curves.

2. Forcible Fracture. *a.* Manual; *b.* Instrumental.

a. Manual fracture.—A strong surgeon can usually break the bone of a child under three years of age, especially if the knee be brought into use as a fulcrum, but the point of fracture is uncertain. The result is a simple fracture.

b. Osteoclasis.—The osteoclast applied to the thigh is a definite and comparatively certain and exact instrument in determining the point of fracture; but in the leg the sharp tibial edge renders the employment of much force a dangerous procedure as regards the life of the soft parts.

3. Osteotomy. *a.* Simple; *b.* Cuneiform.

a. Simple section of the bone with the osteotome, although it produces a compound fracture, is, practically, almost subcutaneous, and if done with thorough asepsis is rarely followed by suppuration. It is applicable to all except the very worst cases of deformity, since even sharp angles of bone are speedily enclosed in the calus. Suturing of the divided bone is rarely necessary.

b. Wedge-shaped osteotomy is applied to severer grades of deformity. This operation is much more likely to be followed by suppuration, but with strict asepsis such an accident is rare. Plaster-of-Paris furnishes the most convenient form of splint. Osteotomy offers the simplest, surest, and most satisfactory results in anterior tibial curves. Illustrative cases were described and the details of the antiseptic operation were fully enumerated.

Dr. Ap Morgan Vance, of Louisville, Ky., then read

A CLINICAL REPORT OF EIGHT CASES OF FEMORAL OSTEOTOMY

for correction of deformity resulting from hip disease in five of the cases, and knee-joint disease in the remaining three. He advocated the subcutaneous method as being better than the operation by open wound, stating that he would break a man's femur subcutaneously, with as little misgiving as to the outcome, as he would divide the tendo Achillis. All of the cases reported had practically reached adult life, the youngest being fourteen and a half years of age, the oldest thirty-two years. The operation as done by Dr. Vance is somewhat simpler than that described by others, and is as follows (quoting from one of the cases): The patient was anæsthetized and turned upon his right side. A block of marble, well padded, was pressed tightly upward on the inner side as high as the perineum would allow. The chisel was entered just below the trochanter, the edge of the blade being in the axis of the limb. It was then sunk by steady pressure to the bone, then turned with the edge across the bone, and driven, with sharp strokes of the mallet through until its hard substance on the other side was reached and partly entered. The direction was then changed, and the same amount of cutting done in several directions until sufficient weakening had been produced to insure our being able to complete the fracture. Without removing the chisel, the edge of the padded block was placed opposite it and rested on the table, this acting as a fulcrum at the weakened point. The pelvis being fixed by an assistant, a quick and forcible depression of the lower end of the femur completed the fracture. The point he emphasized in regard to the knee cases is, that it is better to correct by a bone section the deformity in a class of cases which had been very unsatisfactory in any other way unless excision is done.

The President exhibited an

OSTEOCLAST

made by Colin, of Paris.

The discussion of Dr. Willard's and Dr. Vance's papers was participated in by Drs. Gibney, Bradford, Moore, Phelps, and Shaffer.

Dr. Henry Ling Taylor, of New York, read a paper on

THE MECHANICAL TREATMENT OF SENILE COXITIS.

By senile coxitis the author understands a rheumatoid affection of the hip-joint occurring in old people, and characterized by pain, stiffness, muscular spasm, and disability; one never showing a tendency to suppuration. It may or may not be associated with similar trouble in other joints. The point made was, that some of the cases which have resisted the ordinary medicinal and dietetic treatment, and in which the hip-joint disorder is of such a grade as to practically incapacitate them from locomotion, may still be very much benefited, and the comfortable use of the limb restored by resorting to mechanical treatment. Two cases, in females, aged about fifty-seven years, were cited. The patients were put in bed with the long traction splint and sixteen pounds extra weight attached, for four to six weeks; then the jointed supporting splint (Dow's) with perineal strap was applied and worn for about two years.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Wednesday, September 19th—Second Day.

Dr. John Roe, of Rochester, read a paper on

INTERNAL ŒSOPHAGOTOMY, WITH REPORT OF SUCCESSFUL CASES.

In treating strictures of the œsophagus that do not readily respond to attempts at dilatation, the author prefers to operate according to a method devised especially for the purpose of avoiding the dangers attending the forcible stretching or tearing of the dense tissue in performing divulsion, and the comparatively deep cutting in the operation of internal œsophagotomy as usually performed, where one or two incisions must yield all the increase in size needed at the seat of the stricture.

They are necessarily cut or stretched into deeper tissue than when the stricture is dilated by the aid of multiple incisions, individually insignificant, because but a fraction of the effect is demanded of each. The stricture itself has more weak points that must yield to subsequent dilatation, and give more rapid results. The histories of several operations, that had proved most successful, were read for the purpose of demonstrating the satisfactory results obtained by this method of operating and dilating

Dr. Beverly Robinson, of New York, read a paper on

DYSPEPSIA AS REFLECTED IN THE MUCOUS MEMBRANE OF THE UPPER AIR-PASSAGES.

In this discussion, the importance of giving proper attention to the condition of the patient's general health was thoroughly demonstrated by the numerous examples cited. This fact is now more thoroughly appreciated by those interested in special branches. The most successful specialists are not always those who made their choice while yet students and strove to adapt their whole course of study, and even their hospital experience, to that choice, but those who have had careful training in general practice first.

Laryngologists, first of all, seek the main cause of trouble, and are always on the lookout for any condition of affairs that may exert the least undue influence. We must see that the patient's general health is at its normal standard, and that no disease of other or distant organs shall remain neglected.

Catarrhal troubles are sensitive to reflex influences whenever other organs are affected to any extent, and whenever the nutrition and general tone of the system is interfered with. Next to local causes, it is a frequent source of the origin and aggravation of catarrhal trouble. Chronic indigestion presents many examples of this, both through reflex influences or by its disastrous effects on bodily nutrition. Cases daily appear where we must first improve these conditions by tonics, etc., for restoring appetite and digestion. Numerous cases presented, where obstinate catarrhal conditions would not yield, and all methods of treatment failed as long as stomach and alimentary canal were out of order. Other cases brought to notice, where the condition of the alimentary canal was proved to be alone responsible for their origin as well.

Dr. Harrison Allen, of Philadelphia, presented a communication on

THE ANATOMY OF THE NASAL CHAMBERS.

Dr. Allen's anatomical demonstration was most concise and thorough. The whole subject was covered systematically, and thoroughly illustrated on all important points by large numbers of prepared specimens and dissections. The field had been broadened by the amount of original work, the result of which was very manifest in his paper. Many points, to which proper attention had scarcely been given heretofore, were emphasized by the abundant material for demonstration. One fact thus treated was the difference in conformation between the right and left nasal cavities, proved both by specimens of bone and in the flesh. Statistics prove perfect symmetry of cavities and septums to be most rare. Deflection to some slight degree is all but universal. Fewer of these are congenital than has hitherto been proved. The habitual position during sleep is one prevalent cause. Illustrated by specimens of skulls, accompanied by statistics which resulted from the examination of large numbers, and others collected by different observers.

Dr. Thomas R. French, of Brooklyn, read a paper entitled

A PHOTOGRAPHIC STUDY OF THE LARYNGEAL IMAGE DURING THE FORMATION OF THE REGISTER IN THE SINGING VOICE.

By means of lantern slides, a large number of instantaneous photographs of the larynx, while in the act of forming different notes, were thrown upon a screen and analyzed in full by Dr. French. One point shown very clearly was the very sudden and radical change in the form of the larynx and position of vocal cords the instant a break occurred, as higher notes were taken one after another, until the singer was forced to change the tone or quality so as to take the note with greater ease, as when forced to change register from chest to head notes. With lower notes the cords were longer, more lax, and less closely approximated. As each higher note was taken, the cords appeared tenser and with more closely approximated edges. Just before the break would occur, apposition of anterior portion of cords formed a stop and allowed vibrations of the posterior portions only. The instant the break occurred there was a sudden change in the shape and appearance of larynx, through different tension of the muscles; cords again separated whole length, approximating their position as shown while taking lower notes of previous register, and following the same changes of tension and apposition of their edges until next break occurred. After both these breaks the cords repeated their former changes, but in a larynx adapted to higher register. The analytical study of these changes should be of great value to thoroughly scientific musicians.

It clearly explained how the cords were spared the excessive strain of high notes, by this break or change of register.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

Wednesday, September 19th—Second Day.

Dr. E. T. Bruen, of Philadelphia, opened the discussion on

THE RELATIVE IMPORTANCE OF DIFFERENT CLIMATIC ELEMENTS IN THE TREATMENT OF PHTHISIS.

Exact statistics on this subject are still wanting, and it is difficult to decide on the relative importance of different climatic elements. Those elements are most important which fortify the body against disease. In disseminated forms of tuberculosis the climatic treatment is often of benefit. No one climate is beneficial to all cases; some improve most on the seashore, others most in the mountains. Sunshine, however, is always beneficial, and overcrowding should be avoided. Sunshine, plenty of fresh air, and purity of the atmosphere, are the important elements in climate for the treatment of phthisical cases. Porosity of soil is of more importance than dryness of the atmosphere; in fact, the latter usually accompanies the former. Equability is not always of importance, as many cases do well where there are sudden changes of temperature. Pure air, abundance of ozone, absence of dust are important, but rarity is not always beneficial, and sometimes positively harmful. The value of rarity of the atmosphere has been overestimated.

Dr. V. Y. Bowditch, of Boston, continued the discussion. The word phthisis covers a variety of diseases, and this is the cause of considerable confusion upon this subject. Elevation and dryness of soil and of atmosphere are important elements in the treatment of incipient phthisis according to most authors. He questions if the value of elevation has not been overestimated. The importance of sunshine, pureness of air, and dryness are too evident to need discussion, and although some cases do well in moist climates, it is the exception. Sea-voyages, however, are often beneficial. He recommends the establishment of sanitariums in proper localities.

DR. F. I. KNIGHT, of Boston, read a paper on

INDICATIONS AND CONTRAINDICATIONS FOR ALTITUDE IN THE TREATMENT OF PHTHISIS.

An out-door life in a pure air is the most important thing in the treatment of these cases. He discusses the residence of such patients at altitudes of from four thousand to six thousand five hundred feet. He thinks such altitudes are not suited to patients over fifty years of age, nor for patients of a neurotic temperament. In many cases where quiescence in the morbid processes exists, high altitudes are beneficial. Patients with large cavities or hectic symptoms should not be sent to high altitudes. Cardiac dilatation, and in most cases hypertrophy, contraindicate high altitudes; murmurs, however, are not always contraindications. Some persons with excessive bronchial irritability do better at low levels.

DR. W. A. JAYNE, of Georgetown, Col., read a paper on

THE CLIMATE OF COLORADO.

There is an exceptional combination in the climate of Colorado of those elements which enable those living there to spend most of the time in the open air. Those first coming there usually experience increased action of the heart, and sleeplessness and nervousness; but these symptoms usually pass off in a short time. Sometimes faintness is also experienced. While the value of the purity of the atmosphere cannot be overestimated, he attributes its chief value to the rarefaction.

DR. SOLLY opened the discussion on the subject of

ALTITUDE AND CLIMATIC CONDITIONS IN THE TREATMENT OF CONSUMPTION.

He disagreed with Dr. Bruen that altitude was of little value comparatively in the treatment of phthisis. He thinks where there is lack of chest expansion altitude is most beneficial. He does not think active conditions, ulcerations, and hectic are always a contraindication. He has seen cases of ulceration in laryngeal phthisis which have healed in Colorado.

DR. DENNISON, of Denver, thinks that altitude is an important element in treatment of phthisis, not only on account of the rarity of the air but also on account of the cold. The cold air, breathed into the lungs and raised to the temperature of the body, has a mechanical action in the expansion of the lungs.

DR. KRETZSCHMAR, of Brooklyn, thinks that altitude has considerable influence on the development of phthisis. He believes in out-of-door life, but rather in rest than in exercise out of doors.

DR. FISK, of Denver, spoke of the value of sunshine, and said that a greater percentage is usually found at high altitudes than at low levels. He insists upon a long residence in high altitudes.

DR. W. T. FORD, of Utica, thought that altitude was not an important element in the treatment of phthisis, but that pureness and dryness of air and out-door life are the important elements.

DR. TAYLOR, of San Antonio, Tex., thought that altitude was not, but that dryness was, an important element. He instanced the number of cases benefited by residence in Texas at an elevation not exceeding two thousand feet.

DR. BRUEN, in closing the discussion, said that he did not deny the value of the mechanical aids of a high altitude in certain cases, but what he wished to emphasize was that many cases were not proper ones for the high-altitude treatment.

DR. W. T. FORD, of Utica, read a paper on

AN EPIDEMIC OF CEREBRO-SPINAL MENINGITIS IN CENTRAL NEW YORK.

He instanced several epidemics which seemed, when they came on, to take the place of other inflammatory diseases prevailing at the time. The inferences drawn from nine epidemics were that damp, wet weather and insanitary conditions favored the epidemic, and that dry weather, either cold or warm, was unfavorable to its development.

DR. E. TRUDEAU, of Saranac Lake, sent a communication entitled

AN ENVIRONMENT EXPERIMENT REPEATED,

which was read by DR. A. L. LOOMIS. Former experiments of inoculating rabbits in the lungs with pure culture of the bacillus were repeated. Of six rabbits two failed to become infected, and in two the lesions were only local. From a comparison of these and former experiments, it would seem that the amount of virus injected at one time has a considerable influence on the result. He draws the conclusion from his experiments that the best prospect of success in the treatment of phthisical cases lies in placing them in a condition of favorable environment.

DR. SANSOM, of London, thought that we may now consider the bacillus as the cause of tuberculosis. He believes that tubercular lesions are sometimes curable, as, for example, tubercular meningitis. He believes the danger in such cases lies not so much in the presence of bacilli as in the presence of septicæmia, which is so apt to be present.

DR. WILLIAMS, of New York, suggested that the difference in virulence of cases, not only of tuberculosis but of cholera and other infectious diseases, may depend upon some difference in the germs themselves, and that some experiments should be made with reference to this point.

DR. C. C. RICE, of New York, presented the

REPORT OF THE COMMITTEE ON MINERAL SPRINGS.

An attempt was made to make some classification of the mineral springs with reference to their therapeutic results. Over eight hundred letters were sent out to the different springs. The answers, in the majority of cases, were unsatisfactory, often unscientific, and answered by hotel-keepers or owners of the springs. Tables were given of the uses and the mode of using the waters. To obtain more satisfactory results, it is recommended that a committee of two persons in each State be formed, and that further investigations be carried on. As an indication of the work to be done, it may be stated that nine-tenths of the mineral waters of the United States are still unanalyzed.

DR. WILLIAM PEPPER, of Philadelphia, opened the discussion with remarks on the

THERAPEUTIC VALUE OF MINERAL WATERS IN GASTRO-HEPATIC DISEASES.

This country is richer than any other country in mineral springs, but the reliable analyses of these springs are very few. He emphasized their value in removing effete material in these diseases. Gastric atony, catarrh, dilatation, congestion of liver, gall-stones, abdominal engorgement are all benefited by their use. It is important to consider the time and mode of administration. The diet and the exercise to be taken during their administration are extremely important; he recommends when to be given with the water treatment.

DR. A. H. SMITH, of New York, made some remarks on

THE USE OF MINERAL WATERS IN URINARY AND ARTHRITIC DISEASES.

Those waters containing the least amount of mineral matter are the ones most beneficial—examples of which are the Gettysburg water and Clysmic. The frequent use of mineral waters containing much solid matter by persons in health irritates the kidneys and may even produce disease.

DR. W. C. VAN BIBBER, of Baltimore, made remarks on

MINERAL WATERS IN MALARIAL DISEASES.

He recommended the water of the Greenbrier White Sulphur Springs, to be used from two to four weeks.

Two to four glasses should be taken before breakfast; a bath in the middle of the day with a couple more glasses of water, two more in the afternoon, and two more before retiring. He has seen most excellent results. He also recommends some of the Saratoga springs for cases of chronic malaria.

AMERICAN PHYSIOLOGICAL SOCIETY.

WEDNESDAY, SEPTEMBER 19TH—SECOND DAY.

DR. H. S. SEWALL, of the University of Michigan, read a paper prepared by himself and ELMER SANFORD, B. S., entitled

A PLETHYSMOGRAPHIC STUDY OF THE VARIOUS CHANGES OF VOLUME PRODUCED IN THE HUMAN FINGER AND ARM BY VARIOUS METHODS OF ELECTRICAL STIMULATION.

The varying volume of the finger and forearm corresponding to the vaso-motor changes was recorded by use of the plethysmograph. The electrical stimuli were applied directly to the finger, or, in the case of the arm, to the elbow, over the seat of the ulnar nerve. The following forms of stimuli were used, viz., the induced current produced by Bohr's pegged cylinder interrupter, the continuous galvanic current, the interrupted galvanic current, the "gliding" current—*i.e.*, one the intensity of which can be rhythmically decreased or increased at will. The special apparatus employed for this purpose is described in the paper. Only comparatively weak currents were used. The effects obtained were simple dilatation, simple contraction, dilatation followed by contraction, and contraction followed by dilatation.

In general, the form of the current had little influence on the result. The constant galvanic current was an exception, and usually caused contraction, or expansion followed by contraction. It must be noticed, however, that this current was used in greater strength than the others. The feeble gliding current and feeble induction current showed a tendency to produce contraction followed by expansion.

The effect of a current seemed to be proportional to the strength of the subjective sensation, the sensation being influenced more by changes in rapidity of interruption than by the strength of the current. This being stated, it may be said that there was a distinct relation between the strength of the stimulus and the vaso-motor effects produced. Feeble currents, which give only vague sensations, produced the most expansions or contractions followed by expansions, and the least simple contractions or expansions followed by contractions. With increase of the strength of the current the per cent. of the contractions followed by expansions increased, and finally simple contractions predominated. With interrupted currents dilatation was obtained with currents which were too weak to excite sensations.

No relation was found between the rate of stimulation and the activity of the vaso-constrictor and vaso-dilator mechanisms. A slight difference was found between the influence of the anode and cathode over the vaso-motors; the anode tending to cause simple expansion or contraction followed by expansion, while the cathode produced contraction or expansion followed by contraction. This result is probably due to the increased sensation caused by the cathode. The vaso-dilators appear the more subject to fatigue.

In most experiments a double effect was noticed during stimulation, usually contraction followed by expansion, less commonly expansion followed by contraction. After cessation of the stimulation, hyperdilatation was seen more commonly than contraction.

Several of the facts developed make it probable that the action seen in the experiments was reflex, viz., the results were obtained with weak currents; nearly the same results were obtained from finger and forearm; a latent period of one or more seconds preceded the effect; and the results could be largely predicted from the sensations. It is already known that the volume of one arm decreases when the other is dipped into cold water, and that it is increased when the other is dipped into warm water; and the authors found, in addition, that electric induction stimulation of the face, arm, or leg was followed by a contraction, and then a more persistent expansion of the arm. These results are very suggestive of the semi-pathological phenomena of taking cold.

The authors concluded that the vaso-motor disturbance produced by comparatively feeble stimuli is due, not to a direct influence of the irritation upon the motor mechanisms of the part excited, but to a disturbance of the general vaso-motor system caused reflexly.

DR. BOWDITCH agreed with Dr. Sewall that the results which he obtained were due to reflex action. He said that, in the experiments which he and Dr. Warren had made in Boston, they did not see expansion followed by contraction. Dr. Bowditch was sure that the changes which he and Dr. Warren found were not reflex phenomena. The time preceding the change of volume found by Dr. Sewall strongly suggested that the action was reflex. This interval was much shorter than that found by Dr. Bowditch and Dr. Warren.

DR. WARREN stated that in the experiments which he had made with Dr. Bowditch the nerve was cut, and no change was seen in the other leg; therefore their results could not have been reflex.

DR. ISAAC OTT, of Easton, Pa., read a paper on

FEVER.

Dr. Ott's results were based on experiments on animals. Of eight experiments upon the lower animals, five showed increased production of heat, and three showed diminished heat production, while heat dissipation was increased in four and diminished in four. The fever was produced by injecting putrid blood subcutaneously and by the jugular vein. The fever was studied for two days, during day and night. Dr. Ott believes fever to be due to an agent which, either developing within or coming from without, deranges the harmony of the thermotaxic, thermogenic, and thermolytic apparatuses, so that the metabolism of the food and tissues is increased; and this incr변ment may equal that produced upon a full supply of food, but usually is greater than that generated upon a restricted amount of nutriment. The fever agent so alters the relation of heat production to heat dissipation that a high temperature ensues. Exceptionally fever is due to an alteration of the balance between heat production and heat dissipation resulting from a diminution of heat production and heat dissipation. The four basal centres play the most important part in the production of fever.

DR. H. C. WOOD said that the word fever is often used as if it only meant a rise of temperature above the normal, while clinical experience shows that there may be an increased metabolism without a rise of temperature. The temperature of the body depends on the relation of the heat production to the heat dissipation. In fever there is a general increase of metabolism, but this increased waste is often accompanied by a lower temperature, the heat production being masked by the increased heat dissipation. In advanced typhoid not infrequently a sudden fall of temperature is seen. This is no sign, however, that heat has ceased to be produced; it is much more probable that it has been rapidly thrown off. If by fever is meant an alteration of tissue metabolism, we may have fever with high or with low temperature. Dr. Wood urged the danger of carrying over to man the conclusions reached by experiments on animals. He said that there was little reason to suppose that the heat-regulating apparatus was as perfect in fur-bearing animals, for instance, as it was in man.

DR. WILLIAM WELCH remarked that, though clinically it was necessary to take the temperature as a criterion of the febrile state, in physiological work the results of direct calorimetric methods ought always to be controlled by indirect calorimetry, *i.e.*, by the study of the gaseous exchange. He said that the changes caused in an animal by the injection of putrid fluids could not be regarded as true fever. He had seen in his experiments an unaccountable increase and decrease of temperature when putrid fluid had been used, and he doubted whether results obtained by this method were reliable. He said that he knew of no way of producing a fever, such as is seen clinically.

DR. H. U. MARTIN inquired whether in hog cholera, for instance, the temperature rose as much as it was often seen to do in man.

DR. WELCH said that it did not; and when cultures of hog cholera were injected into a rabbit the most conflicting results were obtained.

DR. HARE stated that in two sets of experiments made at different times, in which peptones from the same specimen of pepsin was injected into animals, he had found at one time a rise and at the other a fall of temperature.

DR. BOWDITCH called attention to the fact that though the quantity of food ingested undoubtedly influenced heat production it nevertheless caused no rise of temperature. On the other hand, in fever the high temperatures often seen cannot result from heat production alone, for the metabolic activity would have to be many times that of health, and the whole body would have to be burnt up to supply such an amount of heat. Unquestionably the lessened heat dissipation plays a most important part in the elevation of temperature seen in fever.

DR. R. H. CHITTENDEN, of New Haven, Conn., read a paper entitled

THE INFLUENCE OF ACETANILIDE OR ANTIFEBRIN ON PROTEID METABOLISM.

The paper was based on experiments made by H. C. Taylor, Ph.B. The observations were all made on one healthy man. It is to be remembered that the disease may make the organism more susceptible to the influence of the drug.

The young man was first brought into a condition of nitrogeneous equilibrium, which condition was maintained by appropriate diet throughout the experiment. The excretion of nitrogeneous matter was arrived at by determining the amount of urea and uric acid in the urine. The drug was given in gradually increasing doses, for nine days, at a time which would not interfere with digestion, until a slight approach to cyanosis was seen. In all 13.3 grains were administered. No disagreeable effects on the digestive, circulatory, or respiratory system resulted, though there was decided blueness of the lips and lividity of countenance.

A second experiment on the same man was made in which 13.9 grains of the drug were given in seven days. This also resulted in the same approach to cyanosis. Weinstein considers that aniline is set free from the acetanilide and that it causes a decomposition of the hæmoglobin. The writer was uncertain as to whether this was the cause of the cyanosis observed.

In these experiments the excretion of urea was not greatly affected. In both, however, a slight increase was seen. The writer therefore concluded that acetanilide slightly increases the excretion of urea, but does not greatly increase proteid metabolism. This is also indicated by the lack of corresponding changes in the amount of sulphur excreted. The excretion of phosphorus was also unaffected. The excretion of uric acid was decreased, and this appeared to be the most characteristic effect of antifebrin, so far as its influence on proteid metabolism is concerned. The amount of water excreted was apparently uninfluenced.

Owing to the absence of the writer the discussion of the paper was omitted.

MR. VICTOR HORSLEY, F.R.S., of London, Eng., described to the Society some of the experimental work which he and Mr. Gotch, of Oxford, had done upon

THE PART TAKEN BY THE CELLS OF THE CORTEX AND OF THE SPINAL CORD IN PRODUCING THE MUSCULAR CONTRACTIONS WHICH ARE SEEN TO FOLLOW STIMULATION OF THE CORTEX CEREBRI.

When the cortex is stimulated one sees a tonic contraction of the muscles, which usually lasts while the stimulation is continued. On removal of the stimulus the tonic contraction ceases, and is followed by a clonic contraction. It was thought that if one could study the electrical changes occurring within the pyramidal tracts at some point between the cortex and the spinal centres which correspond to the limb stimulated, one might ascertain whether both the tonic and clonic contractions were due to impulses coming from the cortex. With the aid of non-polarizable electrodes and an excessively delicate capillary electrometer, this was actually accomplished. The spinal cord was cut through at a point above the region containing the centres of the lower extremities and the electrodes applied. After the demarcation current resulting from the injury had been compensated, the cortex was stimulated, and the changes exhibited in the height of the mercury column of the electrometer were recorded photographically. The record showed that in exact parallelism to the mass movements of the convulsed muscle there was a persistent negative variation, lasting as long as the stimulus was applied, and that this was succeeded by clonic or rhythmical variations after a short latent period had elapsed. The variations recorded were not dependent upon a general disturbance of the spinal cord, resulting from the stimulation of the cortex, as was proved by the fact that the column of mercury did not change its position at all when the cortical centres for the upper extremities were stimulated. The negative variations in the pyramidal tract thus revealed the character, and in part the amount, of the influence sent from the cortex down the pyramidal tract. These experiments showed that both the tonic and clonic contractions seen in cortical discharge was the direct result of the activity of the cells of the cortex, and that the spinal cord possessed no autonomical influence on the character of the Jacksonian fit.

DR. H. C. WOOD asked whether the clonic stage was always present in epileptic convulsions.

MR. HORSLEY replied that in experiments it was rare to see tonic contractions without following clonic contractions, but that it was possible that this might be observed clinically. Further, Mr. Horsley said that in their experiments Mr. Gotch and himself had failed to discover changes in the nerves when the cortex was stimulated. They thought that it was probable that the instrument was not sufficiently delicate to indicate these variations. The cross-section of the cord is so much larger than that of the nerve that there is obviously more opportunity for the electrodes to be influenced.

In reply to a question from Dr. Bowditch, Mr. Horsley said that when the nerve was directly stimulated a change was seen in the electrometer, even when a single induction shock was used.

DR. BOWDITCH remarked that the failure to get a change in the nerve when the cortex was stimulated suggested that the influence from the cortex was dispersed and partially lost in the cord.

DR. HORSLEY said that he thought this to be the true explanation, believing the loss to be due to resistance in the anterior cornual corpuscles.

DR. BOWDITCH, after thanking the reader of the paper in behalf of the Society, expressed his belief that the method which had been described by him might be of great service in tracing the course of nerve-fibres.

Dr. Warren Plimpton Lombard, of New York, read a paper on

THE NATURE OF THE KNEE-JERK.

As the result of his experiments, the writer concluded that the theory that the knee-jerk is a wholly peripheral process is untenable, because it does not satisfactorily explain the dependence of the phenomenon upon the spinal cord. He could find no proof that muscle-tonus is continuous, and no proof that the irritability of a muscle to mechanical stimuli is dependent on its tension, both of which assumptions are necessary to the theory that the muscle is stimulated directly by the blow on its tendon. On the other hand, he discovered that the size of the knee-jerk is independent of the tension of the muscle, and that reinforcing actions do not alter the tension or irritability of muscles. In addition to this, he discovered that the blow on the ligament, whenever the subject is the least excited, calls out a contraction of the flexor as well as the extensor muscles of the knee. This contraction of the flexors is not due to direct stimulation of the muscles by a strain brought upon them by the sudden extension of the knee seen in the knee-jerk, because it sometimes occurs actively when the knee has extended very little, and because, although the irritability of the muscles does not alter within short intervals of time, the contraction of the flexors may be present or absent, regardless of the amount to which the knee is extended. These results seemed to the writer to be only explicable on the theory that the knee-jerk is a reflex act. The only argument against this theory is the shortness of the time occupied by the process, and this argument, though important, is far from convincing while our knowledge of reflex times in general is so meagre.

Dr. J. W. Warren, of Boston, read a paper on

THE KNEE-JERK PHENOMENA.

The paper treated of the time relations of the reinforcements of the "knee-jerk." It was the extension of a paper presented by Professor Bowditch to the National Academy in April, and was based on experiments made at the physiological laboratory of the Harvard Medical School. The plan of research was to record a number of knee-kicks with and without a reinforcing squeeze of the hand, in response to a signal given at varying intervals from the blow on the tendon. The comparison of these "normal" and "reinforced" kicks (some twelve thousand having been taken from eight different persons) was exhibited in the form of curves. It was shown that, when the voluntary muscular movement occurred within a few tenths of a second of the blow on the tendon, the result is usually an increase in the size of the kick; but, as the interval becomes greater than 0.3 to 0.4 of a second, the reinforcement becomes negative, the kick growing smaller. This inhibition of the kick persists for some time, but there is a gradual return to the normal, so that for intervals of 2.0 seconds and more the reinforcing squeeze has no marked effect. In these tabulations those kicks were omitted for each interval where the reaction-time of the squeeze was so great as to be suspicious. Another set of curves (made up from observations on two persons) was shown, in which all the reinforcements were grouped with reference to the size of their reaction-times and not according to the intervals. Here again it was shown with greater exactness that, when the reinforcing squeeze is so given that only a brief space of time lies between the act and the blow on the ligamentum patellæ, the result is an increase of the kick, a positive reinforcement; but this gives place to a decrease of the kick as the intervening space of time grows larger, *i.e.*, the reinforcement becomes negative. These curves are of the same character as those resulting from a comparison of the intervals alone. Dr. Warren was inclined to consider that his results were due to a true reinforcement and a true inhibition of the quadriceps, and not to the action of antagonistic muscles; but admitted that the method used, of recording his experiments on a slow cylinder, did not permit a complete exclusion of such an explanation, although a quicker cylinder would doubtless show the influence of the antagonistic muscles if such were in play.

Dr. H. C. Wood said that to disprove one theory was not to prove another. In case Dr. Lombard was right in his conclusion that the tonus theory of the knee-jerk is incorrect, it was no proof that the knee-jerk is a reflex act. The shortness of the time involved in the process must not be lost sight of. The knee-jerk is quicker than true reflexes. It may be that it is not a reflex act, and yet is not connected with the tension of the muscle. It is not unlikely that the irritability of the nerves in the sarcolemma of the muscle is dependent on the spinal cord, and that the knee-jerk is dependent on the irritability of these nerves. Absence of change in the muscle is no proof of absence of change in the nerves.

Dr. Bowditch said that the irritability of the nerve is not lessened for a considerable time after section, yet the knee-jerk is lost immediately.

Mr. Victor Horsley, F.R.S., of London, Eng., said that he thought the evidence to be in favor of the idea that the process is reflex. Apparently, the change from the knee-jerk to clonus is a gradual one, and involves no new process. If this be true, since the oscillations seen in clonus are eight to ten in the second, and the vibrations sent out from the lower centres of the spinal system are also eight to ten in the second, it would seem that both the knee-jerk and clonus were due to the action of cells within the cord. Since the most active knee-jerks are obtained when the spinal cord has been divided high up, Mr. Horsley thought that the reinforcements of the knee-jerk could be best explained as dependent upon a temporary loss of inhibition of the lower centres. He said that we need more information before we can arrive at any conclusion. Mr. Horsley suggested the advisability of studying these phenomena on individuals in the initial stages of anæsthesia. He thought that through such experiments it might be possible to prove the knee-jerk to be a reflex act.

Dr. Lombard said that he thought that the contraction of the flexors, which he had called attention to, threw doubt on Dr. Warren's idea that the small reinforcements which he found were due to an inhibition of the knee-jerk. He admitted that, in experiments which he had seen Dr. Bowditch make on Dr. Warren, he had been unable to detect any flexor contraction, but thought that it might nevertheless have been present, because, in his own curves, he had found flexor contractions recorded in experiments in which he had not seen any indication of a contraction of the flexors. He stated that he was inclined to believe the reinforcements of the knee-jerk to be caused by an overflow of nervous energy from the centres producing the reinforcing action. He called attention to the wide occurrence of associated movements which can be best explained as due to such an overflow. He said that the reinforcement of the knee-jerk appeared to be the result of a positive, and not a negative, influence, and even if it could be proved that there was a withdrawal of inhibition at the moment the reinforcing act was performed, the overflow must also be considered as playing an important part in causing the reinforcement.

Dr. Warren said that he doubted that the small reinforcements which he found were due to a contraction of the flexors, because, as far as he could judge, little or no contraction of the flexors had occurred in his experiments.

Dr. Bowditch said that there was great need of more accurate information concerning reflex times in general. He thought that if a muscle could be stimulated by a strain on its tendon, such reflexes of the muscles of the leg must be called out very frequently, and it might well be that the time involved in the process was less than that of many other reflex acts. He suggested that the overflow theory might explain the negative reinforcements described by Dr. Warren, on the idea that an overflow may be followed by a draining off of nervous energy, so that the process acts at one moment as an overflow and at the next as the reverse. He said that he was inclined to the belief that the knee-jerk is a reflex act, and that the reinforcement is due to an overflow from the centres developing the reinforcing act.

Dr. T. Wesley Mills, of Montreal, Canada, presented a communication, entitled

THE INFLUENCE OF THE NERVOUS SYSTEM ON CELL LIFE.

Dr. Mills expressed the belief that all the nutritive processes of the tissues are dependent upon, and controlled by, the nervous system, the same as function, which is only a phase of the general metabolism, and on account of the scope of the action of the nervous system he would term it a "constant neuro-metabolic influence." The arguments advanced by Dr. Mills to prove the presence and extent of this influence cover so wide a field that no short *résumé* can do them justice.

GENERAL SESSION.

Thursday, September 20th—Third Day.

The closing session of the Congress was held in the Army Medical Museum, which was tastefully decorated for the occasion.

Dr. John S. Billings delivered

THE PRESIDENT'S ADDRESS.

Gentlemen of the Congress: Our articles of confederation require that the President shall give an address. In endeavoring to comply with this regulation I must ask your indulgence, for, while I think I have something to say, I cannot give you such a discourse as would befit the audience, the occasion, and the subject.

The prominent characteristic of the great majority of the societies composing this Congress is that their members have, as a rule, been chosen because they have either made some valuable contribution to medical literature, or have, in some way, rendered aid to the profession; in other words, they are supposed to be men whose labor and thought have not been confined to their own interests, or to those of their own patients. It may, therefore, be assumed that you are all interested in medical science, not merely as a means of giving new modes of diagnosis or of treatment, but also for its own sake, for the sake of knowing, for the pleasure of investigation, and in the hope of helping others, and that, while the majority have devoted themselves more or less to special branches, they have not, in so doing, lost interest in what may be for the general good of the whole profession.

I am here as the representative of the medical departments of the general government, which has need of the best knowledge of all the specialties, and is beginning, in its turn, to do something for each.

The physicians in the government service are all general practitioners, and are expected to have such an education and training as will fit them to deal, alone and without consultation, with the diseases and injuries to which men, women, and children are liable. You have been, and still are, their teachers—in the lecture-room and the hospital before they entered the service—in your text-books, monographs, and contributions to journals or transactions which follow them to their widely scattered posts of duty. They are your warm friends; the more you discover, the greater your skill, the more recognition which your work receives, the better they are pleased.

Within the last twenty-five years the general government has, in its turn, done something for medicine and for you, by founding and maintaining a medical library and museum in Washington under the direction of the Medical Department of the Army.

I have had occasion several times to call attention to the library, which no doubt is that part most immediately useful to physicians, and which has attracted most attention. To-night I propose to speak of the other branch, in whose proper development it is desirable that you should take an intelligent interest, and after giving a brief sketch of the development of modern medical museums we will consider more especially our own national medical collection as it is, and as it ought to be.

The origin of collections of objects of natural history was possibly, as suggested by Beekman, the custom of keeping curious objects in temples; but we have no record of the formation of any collections, specially connected with anatomy or medicine, before the sixteenth century. It is true that human anatomy had been introduced in the schools by Mundinus in 1306, and that no doubt in Bologna, in Paris, and a few other places a skeleton or two was preserved for purposes of instruction; but alcohol was unknown as a preservative before the end of the fifteenth century, anatomical details were of no interest until Vesalius had stirred up controversy with the Galenists, and injected preparations were not thought of until after Harvey's announcement, in 1628, of the discovery of the circulation of the blood.

The introduction of the use of the microscope at the beginning of the seventeenth century, and the collections of preparations for use with this instrument made by Leeuwenhoek and Ruysch, gave a powerful stimulus to formation of museums of this kind. The most famous of these collections was that of Ruysch, purchased in 1717 by Peter the Great, and sent to St. Petersburg. Ruysch was practically the first to prepare injected anatomical specimens for permanent preservation, and, if the stories told of his work are true, he made preparations which have never been surpassed. His museum was a very ornamental one, the bones and skeletons being arranged in various devices, the plants in bouquets, while scattered through the whole were beautifully engrossed sentences from the Latin poets.

The most famous medical museum in the latter half of the eighteenth century was that founded by Fontana, at Florence. This still exists, filling a series of rooms, and consists mainly of wax preparations, beautiful to look at, but inaccurate, and of little scientific value.

During the first half of the present century a number of private collections were formed by anatomists, pathologists, and surgeons. Most of these have become public collections, either by gift or purchase, and the rest have been dispersed or destroyed. There is not in existence, at the present time, any large collection of specimens pertaining to human pathology which is the property of an individual, and is at all comparable to those made by John or William Hunter, Astley Cooper, Howship, Liston, or others. Commenting on this fact Sir James Paget writes me that he does not know of any large private pathological collection, and that he believes the change to be entirely for the better.

The necessities of modern progress in anatomy, physiology, and pathology, have led to the creation of medical museums in all parts of the civilized world. In most of the continental capitals these are connected with universities supported by the State. In Great Britain and in this country they are, as a rule, connected with private, or semi-private institutions for medical teaching. This difference is connected with the relative position which medicine holds in the educational machinery of the State in different countries. Where medical education is furnished by institutions directly supported by the government, the museums, which are a part of the apparatus required, are, of course, also supported by the government.

Evidently the city having the most valuable aggregate of anatomical and pathological specimens at the present time is London, which contains the collections of the

Royal College of Surgeons, of St. Thomas', Guy's, St. Bartholomew's, St. George's, and other hospitals, and of University College, the College of Physicians, and others. The oldest public anatomical museum in London is probably that of St. Bartholomew's, which, in 1726, had a room set apart for the purpose under the charge of John Freke, and which received the private collection of Abernethy. The most important medical museum in the world, and the one which has exercised the greatest influence in giving direction to anatomical and pathological studies, and in serving as a model for the formation of other collections is undoubtedly that of the Royal College of Surgeons of London, the foundation of which was the collections made by John Hunter, purchased by the government in 1799. In one sense it is not a government institution, the funds from which it is now supported not coming directly from government grants; but in another sense it is truly such, since the College may be looked upon as an agent of the government having special charge of matters connected with medical education, as it is the principal examining body for those proposing to practise surgery in Great Britain.

The great value of the Hunterian collection lies in the breadth of its scope, which includes every branch of medical science; but it is pre-eminent in illustrations of human morphology and its abnormities. The museums of the great hospital medical schools are relatively richer in the department of pathological anatomy, specimens of which they have greater facilities for obtaining. Among these there is, of course, a certain amount of duplication of matters of interest; but no two pathological specimens are precisely alike, and the question discussed in the Paris school one hundred and fifty years ago, viz.: "An pro distinctis ægris ægritudines diversæ?" is one that often occurs to a curator as he examines new specimens which differ but little from those already in his collection, but which do differ in some respects, and with regard to which he must decide as to whether, upon the whole, they are worth the trouble and cost of preservation.

Edinburgh and Dublin have also each large and valuable collections pertaining to anatomy and medicine.[1] In Paris the medical museums are those of the Faculty of Medicine, including the Musée Dupuytren, devoted to pathological anatomy, and the Musée Orfila, devoted to human and comparative anatomy, materia medica, natural history, and instruments and apparatus.

Professor Léon Le Fort, to whom I am indebted for data with regard to these collections, remarks that a large proportion of the anatomical specimens of the Orfila museum come from candidates who take part in concours opened for positions connected with the anatomical teaching of the faculty—such as prosectors, demonstrators, etc., each candidate being required to furnish from ten to thirty specimens.

The medical museums of other European countries are connected as a rule with universities, and it is to be remembered that in these the different branches of medical instruction are each both more specialized and more comprehensive than is the rule with us. The professor of anatomy, of physiology, of pathology, has each his own building or institute, and, therefore, each his own museum; and unless this fact be held in view, comparisons between Continental and English, or American, medical collections may give very erroneous results.

With regard to the museums connected with American medical schools I will say little. I am aware that in so doing I put aside a splendid opportunity to enlarge upon the general superiority of all these collections and the peculiar excellences of each, but I think that you all know as much about these as I do, and there is time only for details with regard to the one American museum in which I am specially interested. I will say only that the best museum connected with a medical school in this country is the Warren Museum, in Boston, and that the history of the collections of wax models, upon which several of our museums have expended large sums of money, is very instructive as to how not to do it.

So far as mere number of specimens is concerned, our own national medical collection is one of the eight largest in the world, and is increasing more rapidly than any other.

This collection, known as the Army Medical Museum, owes its inception to Dr. William A. Hammond, one of whose first acts after becoming Surgeon-General, in 1862, was to issue a circular stating that, "as it is proposed to establish in Washington an Army Medical Museum, medical officers are directed diligently to collect and to forward to the office of the Surgeon-General, all specimens of morbid anatomy, surgical or medical, which may be regarded as valuable; together with projectiles and foreign bodies removed, and such other matters as may prove of interest in the study of military medicine or surgery."[1] By the end of the year over a thousand specimens had been collected, and the catalogue printed in 1866 showed that it contained 7,716 specimens. It is not my purpose in this address to trace the history of its development; that must be done elsewhere. It has recently been placed, with the Library, in a conveniently arranged fire-proof building, and on the first of July last contained over 15,000 specimens, besides those contained in its microscopical department, divided as follows:

Comparative Anatomy	1,689
Pathological	8,354
Medals	384
Microscopical Specimens	10,416
Normal Human Anatomy	2,961
Instruments and Apparatus	814
Microscopes	141
Miscellaneous	835

Besides these there are 375 specimens pertaining to normal human anatomy and 726 to pathological anatomy, which are in what is called the provisional series.

It is not, however, by number of specimens that the importance and value of museums of this kind can be judged; and in this case such a comparison would give an exaggerated and erroneous idea of the value of this collection. My object in this address is not to boast of what we have, but to indicate what we want; to point out what a National Medical Museum, arranged to meet the wants and interests of this country, should be, should have, and should do, and to suggest some of the ways in which this is to be brought about.

At first the Army Medical Museum was limited to military medical subjects, but of late years its scope has been greatly broadened, and is now nearly the same as that of the Royal College of Surgeons. It includes human anatomy, physiology, pathology, somatological anthropology, instruments and apparatus, and illustrations of methods of teaching connected with special departments of practical medicine. It does not at present include hygiene or materia medica, except in their immediate relations to the military medical service, and this for reasons which will be stated presently. That our National Medical Museum should be broad and comprehensive in its scope there can be no doubt, its requirements in this respect being quite different from those of collections formed and used more especially for the purpose of teaching medical students. The most practically valuable of these last are those formed by individual professors to suit their own specialties and methods of teaching. They need not, as a rule, be large. I may even say that they should not be large; for the labor of properly preserving a large collection is great, and the student, with his limited time and want of knowledge of what to look for, can examine but few specimens so as to profit by them. For the same reason specimens of rare abnormities, of double monstrosities, etc., are of little use in ordinary medical teaching as given in this country, and are not specially desirable in the museums of our medical schools.

---

[1] I am indebted to Sir James Paget for the information given with regard to the greater number of the British museums. I had originally intended to attempt to obtain such data only from four or five of the largest; but on sending my little list of questions to Sir James, he took such a kindly interest in the matter as to send a copy of these queries to a number of other museums, with the request that they might be answered.

[1] Circular No. 2, Surgeon-General's Office, Washington, D. C. May 21, 1862.

You may have noticed that, in speaking of the scope of our museum, I said it included "human anatomy." This phrase does not mean that it has no specimens illustrating the structure of other animals—for it has many, and needs many more; but it means that in this department its main purpose is not to make comparative anatomy an end to itself by exhibiting all known variations in structure throughout the animal kingdom as a basis for their study in relation to development and environment, causation, and results. In other words, it is not an anatomical museum, but a medical museum. The broad field of general biology, including natural history and comparative anatomy, will ultimately be covered by the National Museum, and in our medical collection it will be quite enough to illustrate human anatomy fully, using so much of the structure of the lower animals as will be useful in explaining why certain parts of the human body are thus, and so, and not otherwise. No sharp line of distinction can be drawn between the field of work of the general, and that of the medical, museum. So far as morphology is concerned, they must necessarily overlap somewhat, since both want a certain number of the same specimens, although using them to illustrate different points of view.

The medical museum should possess a series of specimens showing the normal anatomy of the domestic animals, or of animals used in experimental pathology, pharmacology, or physiology, as a basis for comparison with abnormal or pathological specimens derived from the same animals. It is in the section of embryology, illustrating laws of heredity and development, that specimens from the lower animals are most interesting, and this is especially the case in the study of human abnormities and monstrosities. It is quite possible that to some anatomists it may seem that no limitation should be placed to the scope of the museum in this direction, for it is easy to trace some connection between any variation in structure in any animal and some structure, normal or abnormal, in man, but the limitation is placed, with reference to the work of the National Museum, so as to secure the best results.

The kind of specimens most valued for illustrating anatomy in a museum is now very different from what was sought for in the first half of this century. Dried and varnished dissections, showing blood-vessels, etc., are now looked on as nearly useless, and are kept only as historical relics. Elaborate dissections under alcohol, mounted in opaque dishes, with flat glass covers, and sections of frozen bodies, similarly mounted, are what the student and practitioner most desire to see. In our museum there are some excellent specimens of this kind, prepared under the direction of Professor His, of Leipzig; of Professor Cunningham, of Dublin; and by our own anatomist, Dr. Wortman. These, however, are only samples to show how the work should be done. We require several hundred such specimens to illustrate properly regional anatomy in relation to age and sex, while the possible applications of the same methods to the illustration of visceral displacements, hernias, and deformities of all kinds are boundless. As regards physiology, but little can be done by museum specimens to illustrate function as distinguished from form and structure. The so-called physiological series in the Hunterian collection is a series of organs illustrating variations in different families of the animal kingdom or at different ages; in other words, it illustrates ontogenic and phylogenic development. The thing students or teachers of physiology are most anxious to see in a museum are specimens of instruments and apparatus employed in experimental physiology, or in the measurement of the special work of different organs, or in illustrating lectures on physiology. Illustrations of results obtained in experimental pathology often belong quite as much to physiology; as, for example, specimens of results of Gudden's atrophy method.

The Army Medical Museum has only a beginning of such an anatomical collection as I have indicated as desirable. Like all other museums, it is richer in specimens illustrating osteology than in any other branch of anatomy, simply because such specimens are the easiest to obtain and preserve. We are accustomed to think that human anatomy is nearly exhausted as a field for original research, and that, at all events, every important organ or muscle or nerve has been figured, described, and named. Granting this, so far as the adult is concerned, although it is by no means true even for him, we have still to study the development of each of these organs, or groups of organs, as seen at different ages, and, for some of them, in different races. As fast as these points are seen to be of practical interest, either in connection with diagnosis or the surgical treatment of disease, they are investigated; but an ideal museum should furnish the investigator the means for his researches; and it must, therefore, collect specimens without special regard to what is at present known to be their practical interest. The collection of such series of specimens of each joint, region, and organ, as I have in mind, including sections and dissections at different ages, from the earliest appearance in fœtal life to extreme old age in man, and in many cases in the lower animals, is a slow process. Such specimens, and especially such series of specimens, can only be prepared by a skilled anatomist, and there are few such; hence the formation of our ideal anatomical collection, limited though its scope may be, must be a work of time.

There is ample material and scope for original work for half a dozen skilled anatomists for many years to come to supply the demands of this museum for illustrations of human morphology in its various relations, and it is not desirable to scatter effort over too wide a field.

The pathological section of a medical museum is its main feature, being, as Mr. Flower remarks, the section to which, in the eyes of Hunter and his successors, all others form merely the introduction. It is true that to some physicians specimens in this department seem to have little value; but they are balanced by those physicians whose chief interest in a case of disease is to get a post-mortem. No doubt much of the ancient pathology, and some of that which is quite recent, is comparable to the looking in the dark for a black spot which is not there, but those who despise pathology, and devote their entire attention to symptoms and treatment, err as much on one side as those who talk and act as if a knowledge of pathological anatomy could take the place of clinical experience do on the other. I do not know, however, that the doctrine usually preached, viz., that each man should attain the just mean in his views, is a true one. Certainly it is not the principle on which the universe seems to be constructed; the balance is maintained, not by having everything exactly symmetrical, but by excess in one direction balancing excess in another.

To secure pathological specimens in their most instructive forms for museum purposes requires, in many cases, not only considerable variation from the usual routine methods of post-mortem examinations, but very considerable delay in ascertaining the results. If, for example, we wish the best specimens of the results of cerebral disease, the brain must not be removed and sliced up in the usual manner; it should be hardened *in situ* to a certain extent, and its sections should be carefully considered with reference to their preservation in their relations to each other before they are actually made. There is need of a treatise by a skilled pathological anatomist giving such methods in detail from the modern point of view.

One of the most important sections of our museum is that devoted to microscopy, including normal and pathological histology and photomicrographic work. In the cabinets there are nearly eleven thousand mounted specimens, illustrating almost every field of microscopical research. Many of these were made twenty years ago and more, and were mounted by processes which have not given good results, so that Dr. Gray, who is in charge of this section, estimates that about three thousand will be set aside as worthless; but the rest form a very valuable series, to which additions are being constantly made, and materials for which we are specially anxious to obtain. In connection with this section a series of cultures of chromogenic and pathogenic bacteria is kept up for museum exhibits, and also to illustrate methods of work.

While the great majority of the specimens in a medical museum have some relation to diagnosis, prognosis, or therapeutics, the number of those which are of direct interest to the so-called practical physician is not very great. It includes models and casts illustrating dermatology, morbid growths, the results of amputations, excisions, plastic operations, etc., and instruments, apparatus, dressings, etc., of all kinds. Here also may be classed hospital fittings and furniture, means of transportation for sick and wounded, model cases of instruments, emergency chests, etc. Our medical museum has a fair beginning of a collection of this kind, including over a thousand specimens; but many more are needed to make it reasonably complete. If each medical man who devises a stethoscope, a pessary, a speculum, an ophthalmoscope, or an electrotherapeutic appliance with which he is well pleased, would send a specimen to the collection, its increase would certainly be rapid, and it could always show the latest improvement.

An ideal medical museum should be very complete in the department of preventive medicine, or hygiene. It is a wide field, covering, as it does, air, water, food, clothing, habitations, geology, meteorology, occupations, etc., in their relations to the production or prevention of disease, and thus far has had little place in medical museums, being taken up as a specialty in the half dozen museums of hygiene which now exist.

Our own National Museum of Hygiene, is, as you know, under the direction of the Medical Department of the Navy. It is a very interesting collection of sanitary appliances of various kinds; but it is not well housed, is much overcrowded, and its location is so inconvenient that it receives but few visitors, and, therefore, has by no means the educational influence that it ought to have. It should be provided with ample quarters in the immediate vicinity of the National and of the Army Medical Museums, to both of which it would form a very desirable supplement. In our medical museum, at present, military hygiene only is illustrated, and this only in a few branches, such as hospitals, means of transportation of wounded, etc. As regards materia medica, an exceedingly well arranged collection, including about five thousand specimens, has been formed in the National Museum, mainly under the direction of Dr. J. M. Flint, of the United States Navy. The relations of materia medica to natural history, commerce, and the arts, which are subjects belonging especially to the National Museum, are as close as they are to medicine, and I am very glad that our national collection in this branch is where it is, and under its present management. In the Medical Museum we have a collection showing what is supplied in the way of drugs, instruments, etc., to the medical department of our army, and, as opportunity offers, we shall extend this to include the medical supplies of other armies or services.

The extent to, and manner in, which a medical museum should deal with anthropological and ethnological problems are not questions to be discussed in the abstract with advantage, since the answers must differ greatly according to circumstances. In our National Museums the matter has been so arranged that all material relating to anthropometry, or to real or supposed structural differences in man according to race, are cared for in the Medical Museum, while specimens illustrating manners and customs, implements, weapons, clothing, pottery, etc., are taken charge of in the anthropological division of the National collection.

The Army Medical Museum contains what may seem a large amount of material relating to human osteology, and especially craniology, in its relation to North American ethnology, or the history of the development of different varieties of man on this continent; but it is not actually half large enough to permit of drawing definite scientific conclusions from it. The majority of the crania which it contains have been measured to a certain extent, and the results have been published; but many other measurements are desirable to permit of comparison with series taken elsewhere, and even measurements already made must be repeated by later and better methods. We have been trying some experiments with composite photography and superimposed contour tracings as a means of obtaining typical outlines and dimensions for race groups of crania, and these give promise of good results. If the collections of crania of North American Indians in Boston, New York, Philadelphia, and Washington could be brought together, a very much better average representation of the majority of tribes or groups would be obtained than can be furnished by either of those collections taken separately. By composite photography and tracings, combined with uniform methods of measurement, we can practically bring these collections together, and obtain results nearly as satisfactory as if we had them all in one room. We have also fitted up one large room with instruments and apparatus for anthropometry in its widest sense, including psychophysical investigation, and it is intended to make this a complete laboratory for illustration of methods of work.

In London arrangements have been made to have such an anthropometric laboratory in an outbuilding at the South Kensington Museum. The two things have no connection, and it seems to have been placed there because it would obtain more visitors desirous of being measured and tested than if placed anywhere else. In this laboratory, which is, I believe, essentially the same sort of institution as that arranged by Mr. Francis Galton at the Health Exhibition in 1884, and is planned by Mr. Galton, any person can have the regular series of measurements and tests made upon himself for a charge of six cents. There are difficulties in the way of making a charge for such measurements in a government establishment, and there are also difficulties in undertaking to do such work gratis, chiefly on account of the cost. It is, however, so desirable that it should be done, and the data which such observations systematically carried on for a series of years would be so valuable, not only from a scientific point of view, but for practical purposes in connection with life insurance interests, and very possibly with practical medicine, that we should endeavor to overcome these difficulties in some way, and I think it can be done sufficiently, at least, to stimulate private enterprise in this direction. It is possible that we may yet see in large cities establishments of this kind, directed by skilled and reputable physicians having the confidence of the profession, where not only normal but abnormal conditions can be determined; places where the secretions can be tested chemically and microscopically, ophthalmoscopic and endoscopic examinations of all kinds made, the mode of functioning of muscles and nerves determined, and an authoritative record of the results made for the use of the individual, as evidence of his condition, or for the information of his physician. It would require an already established reputation, and much skill and tact on the part of the director of such a laboratory, with absolute refusal to give prescriptions or advice in any shape, to make it fully successful; but it may be done.

An important feature of our national medical museum should be to show methods of research and of instruction for the benefit of the investigators and teachers of the country. This includes instruments and apparatus, and, to a limited extent, illustrations of the modes of using them and of the results; it also includes diagrams, models, etc., used for illustrating lectures. For example, as soon as Koch's researches became known in this country, physicians, and especially medical teachers who visited the museum, asked if we could show them the apparatus used by Koch and Pasteur in bacteriological work, and eagerly examined the few specimens of cultures on solid media which we were able to exhibit. The anatomist comes to the museum quite as much to see methods of mounting and preservation, as to see the specimens themselves; the physiologist does not expect to see function directly exhibited, but he does hope to find information about kymographs and constant temperature apparatus, and he wants to see whether Kühne's artificial eye is so useful for teaching purposes that he ought to get one to illustrate his lectures.

In what has been said thus far, it is chiefly the utilitarian point of view that has been made use of; but this is by no means the whole matter. No art, and no branch of science should form the sole end and object of a well-balanced life, and there are objects in every large museum which are of great interest, though they appeal rather to the emotional than the intellectual faculties of the spectator. There are many specimens in the Army Medical Museum which I would rather see removed than to lose John Hunter's lancet, which has no scientific interest whatever. So also its collection of between three and four hundred medals and tokens relating to medical institutions or distinguished medical men, or commemorating outbreaks of pestilence or the victories of preventive medicine, is one which should be made complete and fully displayed, though it would not be easy to demonstrate its utility to any one unless he were interested in the history of the struggles and triumphs of the medical profession.

The objects of a medical museum are to preserve, to diffuse, and to increase knowledge. Its conservative function is to form a permanent record of what has been demonstrated and to fix the meaning of terms. Even in my brief experience of thirty years, the terminology of anatomy, physiology, pathology, chemistry, and of most of the specialties has greatly changed, and this not only by addition of new terms, but by the dropping of old ones. To get useful results from the older literature we must know the precise significance of the old words, and, in some cases, the best way to learn this is to examine the specimens prepared by those who used such terms in their descriptions. The specimens in our museum which came from the collections of Professor William Gibson and Dr. Frank Hastings Hamilton are especially valuable, because they were the basis of practical teachings, and should be examined by anyone criticising these teachings.

A large proportion of the pathological specimens in this museum illustrate conditions which now rarely occur, forming a group which it is safe to predict will never be duplicated. It is not only that they were gathered during a great war, but that they illustrate the results obtained when antiseptic surgery, as now understood and practised, was unknown. Never again, I hope, will there be brought together such a collection of the effects of pyogenic micro-organisms on gunshot wounds, especially of bone, as may be seen in its cases.

The museum also preserves, for future investigations, objects whose nature or relations are not understood at the time when they are received, and which occur so rarely that the means of studying them by comparison can only be obtained through such preservation.

Upon the function of a museum as a diffuser of knowledge, as a means of education, it is needless to dwell. That it should also strive to increase knowledge is equally certain. This is to be effected by study and comparison of its materials. The results of such study and comparison of a part of the Army Medical Museum collection have appeared in the volumes of the "Medical and Surgical History of the War." Another part will, I hope, soon be utilized in a study of its collection of human skeletons and crania which has been commenced by Dr. Matthews, of the Army. But a considerable part is as yet only in the stage of agglomeration, and our present business is to collect and preserve, leaving to the future its full utilization.

A medical museum is really used, for purposes of study, by very few persons; but through the teaching of those few its lessons are made known to the whole profession. American physicians in investigating a subject do not, as a rule, think of inquiring as to what museums can show with regard to it, simply because they have not had convenient access to large collections and are not accustomed to make use of them. Thirty years ago we were in much the same situation in respect to medical literature; but as the libraries have grown, desire for bibliographical research has grown also, and I think that in like manner, when we have secured a comprehensive National Medical Museum, it will not only be made use of, but will give a powerful stimulus to the formation and progress of other more special collections elsewhere.

What should be the relation of this central national collection to those formed in different parts of the country, either in connection with medical schools, or with museums of broader scope? Certainly they should help one another, and this can be done in many ways. I do not in the least object to a generous rivalry to do the best work, to have the most instructive and the most artistic preparations. That is a good thing. But I would say to the anatomist of a school, when you have made a preparation which is noteworthy, offer to make a copy for the national collection, where it will be seen by the anatomists of all schools and of all countries. To the pathologist of a medical school I would say, after you have secured type specimens for your own collection, put aside other good specimens for the National Medical Museum, which will furnish you materials for the purpose.

On the other hand, the collections of the National Museum are available for study by any proper person, and its duplicates should be used to aid other museums which may be in special need of them.

In common with several of the largest and most important medical museums, more especially those of the Royal College of Surgeons and of the Faculty of Medicine of Paris, the Army Medical Museum has the advantage of being closely associated with a large medical library which is in the same building, and at present under the same direction. The increased utility and attractiveness which this gives to both library and museum is very decided.

It is true that in some other institutions similarly arranged there has been some grumbling as to the proportion of funds allowed to the museum and to the library, respectively, the museum enthusiast claiming that the librarian would rather have one rare old pamphlet than half a dozen entirely new vertebrates; while the bibliophile is sure that the demand of the profession for access to a full supply of books and journals is much greater than that for access to specimens. I can only say, from my own experience, that one who has charge of a library only, will probably not hesitate to take museum funds, if he can get hold of them, to buy books; but that when one person is responsible for both he will endeavor to give each its fair share of the resources at his command.

If we had to choose between having a great national medical library and a great national medical museum, no doubt most of us would take the library, because it would be of more immediate use to us; but no such unpleasant alternative is forced on us. There is no reason why we should not have both, and we must have both.

I have time for only a very condensed statement of the wants of our National Medical Museum. In the first place, it needs the intelligent interest and friendship of the medical profession of this country. To a very considerable extent it has had this; were it otherwise it would not be what it is, nor where it is. But it needs more of it, and it can never have too much. Every medical man in this country should help a little, and provide for the perpetuation of his name as that of a physician interested in the progress of the profession by sending at least one specimen to it. It is omnivorous in its demands for material, as will be seen by the circular which it has recently issued. But I will name as special wants, human embryos, especially those of a very early age, monstrosities and malformations of all kinds in man or in the lower animals; results of old injuries, such as fractures or dislocations, or of surgical operations, such as excisions, stumps, etc.; injuries and diseases of the eye, ear, and nose; new-growths of all kinds; diseases of the brain and spinal cord; and specimens illustrating the condition of bones, joints, brain, larynx, and other organs in extreme old age.

In the second place, it needs a regular supply of funds from the general government. To form and keep in proper condition such a medical museum as this should be, is a more difficult and expensive matter than those not acquainted with such work would suppose, and the gifts of specimens from the profession must be supplemented by ample means for the preparation, preservation, and proper display of these specimens, and also for the purchase of apparatus and typical specimens of foreign work, in order that the museum may be always able to show the latest state of knowledge and the best ways of doing things.

The annual appropriation for the museum at present is $5,000. This is sufficient, except that the printing of the catalogue, of which I shall speak presently, must be an extra charge; but the medical profession should see to it that the amount is not reduced in the rhythmic spasms of partial economy with which some of our statesmen are afflicted.

The third need of the museum is of a series of the right kind of descriptions of its specimens, given on labels and in a catalogue. Unaided by such descriptions, it has for each man that which he can see in it, and no more. One man will see nothing but an old piece of bone, a shapeless mass of tissue bleached by alcohol, a case of old dingy brass instruments. Another will see in the same things a rare joint atrophy, implying curious abnormal nerve influence; a leprous nodule, whose history, if we knew it, would reach back through the lazar-houses of the middle ages to the far East, and whose bacilli may be the lineal descendants of those that vexed Naaman the Syrian; a case of microscopes illustrating the development of that instrument, from the first rough iron tube of the spectacle-maker of Nuremberg to the delicate and complicated instrument through which we now peer curiously into that world which lies within the world of unassisted vision. By our labels and catalogues we must tell men what to see; but to do this we must first see ourselves. The aphorism that a first-class museum would consist of a series of satisfactory labels with specimens attached means a good deal. Something has been done in this direction, as you will see on inspection of the cases; but I often wonder what sort of labels a man who has spent years in investigating the normal and abnormal structure and relations of one organ would write for our specimen of that organ. Such help as this we need; kindly, truthful criticism, the pointing out of errors and of new points of view for this mass of material.

We also need a series of printed catalogues. One of these should be in the form of compact handbooks relating to particular sections of the collection, and intended partly for the use of visitors while in the museum, and partly as a ready means of letting distant friends know what material it most needs in different departments. It should also print a complete illustrated catalogue of the whole collection for the use of the investigators and teachers of the profession. Congress has been requested to grant authority for the printing of such a catalogue by the Government Printer. The material for it is nearly ready, and it would make three volumes each the size of one of the volumes of "The Medical and Surgical History of the War of the Rebellion."

The museum needs earnest and well-trained students to work up its collections so as to advance knowledge, and, at the same time, to display properly the specimens so as to make them most instructive. To all such students we shall endeavor to afford opportunities for this work. Precisely how this is to be effected is not yet clear, but here is abundance to be done, and there are quite a number of men coming on the stage who want to do such work for its own sake, because it gives them pleasure. Sooner or later we shall have half a dozen or more of specially trained men busy in the laboratories and work-rooms of the museum, each engaged on his own problems, and the whole for the common good.

The medical museum hints at matters which lie outside the scope of known physical and chemical laws. Physicians have not, as a rule, been very virulent theologians; their studies and their daily work tend to give them compensation of bias in this particular, and, therefore, in this age of transition in beliefs, it is not so true of them as of others, that "the old hopes have grown weak, the old fears dim, the old faiths numb." In our medical museum yonder may be found abundant illustrations of the results of physical and chemical actions and reactions upon what was once living matter, and was connected with centres of consciousness, of intellect, of emotions which imply something more than ordinary protoplasm or mere metabolism. It brings together strange company. The men who dwelt on the sides of the Andes in the old Aztec days, the men who built cities in the Gila Valley centuries before the days of Columbus, the Esquimaux, and the Indian of the plains, black and white, red and yellow, all sorts and conditions of men are represented in those bony caskets which once held their centres of life and thought; but now are reckoned only as so many crania in the museum catalogue. The great majority of the pathological specimens imply either suffering or death, or both, of the individual from whence they came. Some of them are the results of intemperance, of lust, of folly and crime; but some are the results of unselfish sacrifice for the good of others, true flowers of blood and pain. A large group of them form one of the relics of an acute paroxysm of disease of a great nation. The old pensioner likes to keep the battered ball which crippled him, and so these relics have an interest beyond that which is purely professional. That the nation is not crippled by its loss, takes nothing from their interest, and the fact that we are physicians does not imply that we look upon them from a medical or scientific stand only. Those of the combatants who survive are now better friends than ever, and the museum specimens, coming as they do from the sick and wounded of both armies, and contributed by both Union and Confederate surgeons, enforce the lesson of the unity of the profession and of its interests, as well as that of our country.

Our museum, like the library with which it is associated, includes all the specialties. No physician is so learned or skilful that he can find no instruction there, and no one is so ignorant that he cannot comprehend some of the lessons which it teaches. Taken together, these institutions should contribute in no small degree to our national prestige, for which eminence in scientific work and teaching is an essential element, and if it be remembered that they are only twenty-five years old, and that during that period we have been making medical history at a tremendous rate, surely some incompleteness and crudeness may well be excused or overlooked.

Speaking in behalf of the army medical department, and for the dead as well as for the living who have been charged with this work, I can truly say that we have been very proud of our charge, and that we have done our best, each according to his capacity and opportunities, to make the museum and library such as a great profession and a great nation have a right to demand.

At the conclusion of the address a reception was given to the members and guests of the Congress and their ladies.

ASSOCIATION OF AMERICAN PHYSICIANS.

Thursday, September 20th—Third Day.

Dr. Edward C. Seguin, of New York, presented a paper on

THE RELATION BETWEEN TROPHIC LESIONS AND DISEASES OF THE NERVOUS SYSTEM.

The author excluded from consideration vaso-motor disorders, and diffused or quantitative nutritional changes, partly because he considers them to be a distinct subject, and partly because their study would be beyond the scope of a short paper.

He divided the so-called "trophic lesions" into two great classes. In one the lesions are probably mostly due to the action of extraneous causes, and are preventable. The second class embraces lesions which seem to be directly due to the nervous disease, and which are its necessary and unpreventable results.

He endeavored to show that lesions of the second class, which alone merit the name of *trophic lesions*, occur in organs and tissues which are anatomically continuous, and whose life (or preservation of structure and function) is associated or interdependent.

He concludes that disease of the nervous system produces true trophic lesions when it interferes with the associated or interdependent life of continuous tissues. This proposition he offered only as a partial and preliminary answer to the question under discussion.

Dr. Horatio C. Wood, of Philadelphia, followed with a paper on the same subject. His propositions and conclusions were as follows: 1. It is physiologically proven that the nervous system directly affects general nutrition. 2. Various lesions are the immediate result of previous nerve disease. 3. In various cases the lesions are not preceded by circulatory disturbance. 4. No known vaso-motor condition is capable of causing many of these lesions. 5. Therefore it is absurd to attribute changes to preceding vaso-motor changes.

Dr. Ord, of London, opened the discussion by stating these so-called trophic disturbances might be produced in three ways: 1, Through disease of the spinal cord; 2, through disease of nerves; 3, in a reflex way. In illustration, he mentioned a case of chronic hypertrophic cervical pachymeningitis in which there was a wasting of the tissue in the digits of the affected arm, and osteo-arthritis; also the case of a man who, through violent exercise, had lost power in his arms, and whose muscles underwent extreme wasting. There was also wasting of the skin. In conclusion, Dr. Ord spoke of the swelling of the joints of women approaching the climacteric. Various other reflex disturbances were referred to.

Dr. Henry P. Bowditch, of Boston, considered that much might be gained by studying the subject on simpler lines; that therefore it would be well to limit the question to a consideration of its relation to muscles, for in muscles we have not two sets of nerves anatomically distinct, at least such are not demonstrable; we have not the "anabolic" and "katabolic," or "metabolic" nerves. It were better to confine the term "trophic" to nitrogeneous metabolism of muscle.

Dr. Ferrier, of London, said that the nervous system has a direct influence on the nutrition of tissue, altogether apart from vaso-motor influence. The influence of nerves is amply demonstrated in the case of muscles; whether it be in the case of the skin is not so certain. Possibly there are centres which preside over nutrition. It is an interesting question whether there are "trophic" nerves apart from motor and sensory.

Mr. Victor Horsley, of London, called the attention of his hearers to the recent and interesting investigations of his friend, Dr. Frederick Mott. To Dr Mott belongs the credit of being the first to show that atrophy is a true active dystrophy and not a mere passive change. By cutting of the cauda equina he demonstrated an atrophy of the femur. The whole of its inner surface was lined with osteoclasts.

Dr. Francis T. Miles, of Baltimore, next read a paper on "The Effect of Concussion of the Spine on the Reflexes."

Dr. W. H. Welch reported the results of experiments relating to the

THYROID GLAND OF THE DOG.

performed by Dr. W. S. Halsted in the Pathological Laboratory of the Johns Hopkins University. Extirpation of both lobes of the gland of the dog was found to be uniformly fatal in from two days to three weeks, with symptoms similar to those noted by previous experimenters. A large number of experiments were performed to test the remarkable statement of Munk that these symptoms and the fatal result are not due to the loss of the thyroid gland, but are referable to some undefined injuries attending the operation of removal. Munk found that eight dogs survived the isolation of the gland by ligation of all of the arteries and nerves entering it, provided the wound healed by first intention. In the experiments reported by Dr. Welch, with strict antiseptic precautions the two lobes of the gland were isolated and all their vascular and nervous connections ligated. Under these circumstances the gland underwent coagulation-necrosis, and although in eight cases primary union of the wound was obtained, the animals died with the usual symptoms of extirpation of the entire gland. These results, therefore, are directly opposed to those reported by Munk.

In order to determine whether, after complete separation of the gland from all of its vascular and nervous connections, the gland could by any possibility escape death, a single lobe was isolated in a large number of cases in the manner described. In all instances, however, necrosis of the gland ensued, and at the most a few follicles in the periphery of the gland escaped destruction.

Extirpation or isolation of one lobe of the thyroid gland, in the majority of cases, is followed by the full recovery of the animal without any of the symptoms peculiar to complete extirpation. In these cases of partial extirpation very interesting and peculiar changes appear in the remaining lobe. These changes, which have been in part mentioned by Mr. Victor Horsley but not described in detail, were exhibited in a series of microscopical specimens. Before describing these changes the structure of the normal gland was explained and exhibited by microscopical slides. Attention was drawn to the characters of the interfollicular cells, to the frequent presence of red blood-corpuscles in the normal follicles, to the development of the colloid material, to nodules of so-called embryonic gland-tissue, and to the existence of colloid material in the lymphatic vessels of the gland.

The changes in the remaining lobe after extirpation of one-half of the gland were recognized in about three weeks after the operation, and were well marked and characteristic after six weeks. There appeared, however, to be no definite relation between the time after removal of one lobe and the extent of the changes in the remaining lobe. The following were the most noteworthy changes observed: The remaining lobe of the gland was two to four times its normal size, its poles less pointed than normal. The epithelial cells of the follicles were increased in size and in number and were arranged in polypoid masses or plicated folds around the lumen, which was diminished in size and irregular in shape. Newly formed capillaries made their appearence in these polypoid masses of epithelium. After a time, in some places, the situation of the original follicle seemed to be occupied by a mass of large epithelial cells pervaded by a net-work of newly developed capillaries connected with those surrounding the follicles. By these changes, in two months after the operation the structure of the gland may be so altered that microscopical sections would not be recognized as derived from the thyroid gland. The colloid substance disappeared or was replaced by a filmy reticulum. In places an enormous dilatation of the capillaries took place. Dr. Welch believed that while these changes were probably to be interpreted as functionally of the nature of a compensatory hypertrophy, the term hypertrophy did not fully characterize the anatomical condition. These changes, resulting in a transformation of the normal structure of the adult gland, may perhaps be best interpreted as a return to the embryonic state of the gland.

In seven or eight cases out of fifty unilateral extirpations death occurred within a month, without any complications to explain this issue, and with primary union of the wound. The animals became weak and cachectic, had often ulcerations of the gums, and in two cases convulsions. In these fatal cases the follicles of the remaining lobe were found nearly or quite devoid of colloid material, and filled with small oval or polyhedrical epithelial cells, without regular arrangement and without new formation of capillaries. Small-celled infiltration of the interstitial tissue was absent.

In two cases, after ligation of everything entering the two lobes of the gland, except the main artery and vein, changes were found similar to the hypertrophic ones already described. Both cases developed symptoms like those of total extirpation. One terminated fatally in two months, the other recovered. These cases suggested the possible dependence of the anatomical alterations upon changes in the nerves supplying the glands.

Dr. T. Mitchell Prudden exhibited a set of microscopic specimens of myxœdema.

Dr. E. O. Shakespeare, of Philadelphia, exhibited photo-micrographs of various micro-organisms.

Dr. Jacobi, of New York, read a paper on

THE PATHOLOGY OF THE THYMUS GLAND.

Because of the great length of the paper only a few extracts were given. The literature of the thymus for the last ten or twenty years treats more of its histology and embryology than of its pathology. The author referred to the fact that there is no certain size of the thymus: that indeed a great many different sizes and weights have been taken to be normal by different writers. Dr. Jacobi referred to the very doubtful connection between an alleged hypertrophy of the thymus and a so-called laryngismus stridulus. Still he admitted there are a few cases in which the sudden death of infants could not be explained any better than by the hypertrophy of the gland. Briefly he alluded to inflammations and suppurations of the gland, and to the occurrence of punctated or larger hemorrhage into the tissue, and to the occurrence of malignant growths in the organ. Among them he mentioned endothelioma, lymphoma, fibroma, sarcoma, carcinoma, and myxoma, which have been described; the majority of them, however, are decidedly doubtful, particularly because it can be proven that a number of these pseudo-plasms did not originate in the thymus, but in the thyroid gland, or in a neighboring lymphatic gland. For the last eight months he had given his particular attention to the study of the thymus, with regard to tuberculosis, syphilis, and diphtheria. The material for the microscopical studies has been gathered from different institutions in New York City. These microscopical examinations were made by Dr. Henry Koplik, in the Laboratory of the College of Physicians and Surgeons. A few of the conclusions arrived at in regard to tuberculosis are as follows:

In cases of tuberculosis of the thymus here presented, tubercle tissue appeared in the following forms:

1. As miliary tubercles, composed entirely of small, round, or polygonal cells, with a reticulum basement substance in the recent state. In the later stages these miliary tubercles or granula may, at their centres, undergo cheesy metamorphosis (coagulation necrosis).
2. Miliary granula are also found which show, in their centres, the presence of giant cells.
3. Large, cheesy areas, in the periphery of which we still find miliary tubercles, or granula, composed of giant cells, around which are arranged spheroidal or polygonal cells in a fine reticulated basement substance.
4. In all cases the arteries of the adjacent areas of the thymus tissue were the seat of a typical endarteritis (in some cases obliterating) of a tubercular character.
5. A very careful and painstaking examination of the above forms showed tuberculosis present in all cases. In most of the above forms we had also the presence of the bacillus in the walls of the arteries and arterioles undergoing tubercular changes, and the lumen of the vessels was the seat of obliterating changes.
6. In the thymus, tuberculosis may appear simply as so-called tubercle tissue, an infiltration of the tissue of the gland or organ with spheroidal or polygonal cells, held together by a delicate basement substance; this tissue has no characteristic arrangement; the arteries in such areas may be the seat of obliterating processes. In all of the cases examined by us there were present the characteristic bacillus tuberculosis.

Syphilis results in the thymus in two changes, both in the accumulation of hyperplastic connective tissue, and, as in one case, in the formation of a gumma. Diphtheria results in general parenchymatous degeneration.

Finally, persistent thymus, found in a man, aged twenty-six, was made the subject of extensive studies, and it was discovered that retrograde metamorphosis was in full progress; the parenchyma being in a condition of fatty degeneration, and the stroma being replaced almost entirely by fat tissue.

The time allotted to the paper was mostly taken up by the demonstration of frozen sections illustrating the normal topography of the thymus; also of photographs of the same, and of microscopical drawings of the pathological changes.

Mr. F. S. Eve, of London, made some remarks on the work of Mr. A. Lingard and himself on

SYPHILIS,

an account of which work was published in *The Lancet* of April, 1886. The bacillus found during their investigations they do not claim to be the specific germ of the disease. Mr. Eve also spoke on the tubercular origin of lupus, and referred to studies of his own in this direction. In one instance he succeeded in producing lupus in a rabbit by inoculation of tissue from a case of the disease.

Dr. William T. Councilman, of Baltimore, presented several microscopic and macroscopic specimens illustrating bovine tuberculosis.

Dr. George M. Sternberg, U. S. A., owing to the lateness of the hour, did not read his paper on

RECENT RESEARCHES RELATING TO THE ETIOLOGY OF YELLOW FEVER,

but described the method followed in these researches, which were carried on at Havana, and stated that he had not arrived at any definite result as to the specific etiological element of yellow fever. He had made many cultures from the blood of persons just dead of this disease, as well as from the liver, kidneys, and urine. The results were negative as regards those made from the blood and urine. From the kidneys and liver numerous organisms were obtained, but in no instance did he obtain the micrococcus of Freire. Various tube-cultures were shown.

The Society then adjourned.

Chordee is best treated, according to Dr. Frank L. James, by twenty minims of the tincture of veratrum viride, taken at bedtime.

AMERICAN SURGICAL ASSOCIATION.

Thursday, September 20th—Third Day.

Dr. George W. Gay, of Boston, read a paper entitled

THE COMPARATIVE METHODS OF TRACHEOTOMY AND INTUBATION IN THE TREATMENT OF CROUP,

of which the following were the conclusions :

1. Intubation may be tried in all cases of croup.
2. It is preferable in young children and in cases in which the tube must be left entirely to itself.
3. It may be resorted to for euthanasia, provided the operator is reasonably expert and can do it without producing collapse.
4. Tracheotomy is called for in those cases in which intubation cannot be done, or in which it fails to give relief, or in which the laryngeal tube is repeatedly ejected, or requires frequent removal for cleansing. It may also be required in those cases in which sufficient food cannot be given while the O'Dwyer tube is in position. It is also preferable in cases situated at a distance from a surgeon capable of introducing the laryngeal tube.
5. The tracheotomy instruments should always be at hand in intubation in case of emergency.

Dr. H. H. Mudd, of St. Louis, said that intubation had been done as a precautionary measure in many cases in which tracheotomy would not have been thought of. Some of the good results of intubation are to be attributed to this fact. In most of his cases of intubation where the patient survived he had found it necessary to resort to tracheotomy ; patients have recovered after tracheotomy where intubation has proved unsuccessful.

Professor Thomas Annandale called attention to the value of the introduction of a tube through the glottis in cases of operation about the throat where there was risk of suffocation or of hemorrhage into the trachea.

Dr. Huber, of New York, had performed intubation in ninety-four cases, with recovery in thirty-seven. He does not operate early. He considers the internal use of bichloride of mercury as of equal importance as the intubation. There is occasionally an advantage in using a small tube with the expectation that it will be coughed out, and with it a portion of the membrane, and affording an opportunity for feeding while the tube is out.

Dr. T. F. Prewitt, of St. Louis, in one case of diphtheritic paralysis had, in order to avoid passage of fluid into the larynx, passed a catheter through the glottis and plugged the larynx with a sponge. This permitted the fluid to go into the œsophagus without risk of entering the trachea. After feeding, the sponge and tube were removed.

Dr. D. W. Cheever, of Boston, advocated the disuse of anæsthetics in cases of tracheotomy, provided proper assistants can be secured. The operation is not accompanied with much pain. By avoiding the anæsthetic many of the risks of the operation are avoided.

Dr. L. McLane Tiffany, of Baltimore, read a paper entitled

PREGNANCY AND OPERATIVE SURGERY—THEIR MUTUAL RELATIONS,

of which the following were the conclusions :

1. Pregnancy is a physiological condition and does not contra-indicate a surgical operation.
2. During pregnancy temporary strain may be exerted on some organ, *e.g.*, kidney, inducing impairment of function.
3. A surgical operation upon a pregnant woman is to be conducted so as to avoid inducing abortion, in itself a serious accident.
4. The main cause of abortion after operation is sepsis.
5. The probability of sepsis after operation is increased if the patient is suffering from disease, either temporary or chronic.
6. Abortion may result from operation—shock, perhaps.
7. Hemorrhage does not seem to induce abortion.
8. Union of fracture may be retarded by pregnancy.
9. Recorded cases show that the unborn child receives no evil impress when the mother is subjected to operation.
10. When a surgical operation upon a pregnant woman is under consideration, the function of all the patient's organs must be carefully investigated and regulated. An operation then conducted antiseptically may be expected to result as though pregnancy were not present.

Dr. J. Ewing Mears, of Philadelphia, thought that while pregnancy was to be regarded as a physiological process in the native woman, it could not be considered in this light in the society woman. Another important point to be considered was whether the operation required was one of expediency or of necessity. In the latter case the surgeon must do his duty, let the result be what it may, but whether or not operations of expediency were to be performed on the pregnant woman was a question only to be decided by further experience.

Dr. P. S. Conner, of Cincinnati, reported a case of

SUBCUTANEOUS OPERATION FOR ANCHYLOSIS OF THE KNEE

in a woman who, it was subsequently learned, was six weeks pregnant. The operation was followed by severe septic infection, but this did not interfere with the normal course of the pregnancy.

Dr. William Hunt, of Philadelphia, raised the question whether or not in the case of inevitably fatal injury of a pregnant woman, as from burns, it was justifiable to run the risk of sacrificing the mother a few days sooner, when by so doing the life of the child might be saved, or must we wait until the last breath has left the body before making the incision ?

Dr. R. B. Bontecou, of Troy, reported the case of a

RUPTURE OF AN UMBILICAL HERNIA

in a woman seven months pregnant. The intestines were out four hours. They were then cleaned and replaced. The woman recovered and a healthy child was born one month later.

Dr. L. McLane Tiffany, of Baltimore, thought that in the case suggested by Dr. Hunt there could be no question as to the propriety of operation. By so doing one life may be saved.

Dr. N. P. Dandridge, of Cincinnati, read a paper on

NERVE-STRETCHING.

The following conclusions were presented :

1. That nerve-stretching should be condemned in all forms of central disease, such as tabes, myelitis, etc.
2. That it offers little prospect of relief in tetanus.
3. That it should be regarded as a reliable method in cases of persistent neuralgia and peripheral paralysis of sensation in the extremities.
4. That stretching the facial is indicated in tic-convulsif.
5. That further trial is justified in reflex epilepsy.
6. That stretching the lingual should be tried in painful affections of the tongue.
7. That resection should always be preferred to stretching in the spinal accessory and in the branches of the fifth nerve except the lingual.

Dr. De Forest Willard, of Philadelphia, read a paper on

NEPHRECTOMY,

for—1, gunshot wound of the kidney; 2, tubercular disease of the kidney.

Case I.—Male, mulatto, aged seventeen, was shot July 10, 1887, at such close range as to burn clothing and skin. Symptoms of internal hemorrhage steadily increased.

Abdominal incision was chosen as best suited to arrest hemorrhage, repair injured organs, and remove clots.

The bladder was found full of blood, but uninjured; ureters the same. The huge hæmatocele was found to be retro-peritoneal, filling all the tissues in the loins and downward into the pelvis. The left kidney was traversed by the ball from the centre of the rim to the infundibulum, and the renal artery and vein cut. Aseptic silk ligatures were applied and the organ removed. The ball had passed behind the peritoneum without injuring other organs, and could not be found. No blood or fæces were found in the peritoneal cavity. The site of the extirpation was thoroughly mopped with sublimate solution, 1 : 10,000, made with boiling distilled water and the abdomen irrigated with hot distilled water. The utmost precautions were taken to prevent infection, and all the dressings were thoroughly antiseptic. The temperature during the next four days varied from 99.4° F. to 101.4° F. About twenty ounces of slightly albuminous urine were secreted daily. The skin was kept active, and no signs of uræmia at any time made their appearance. The patient, however, died of loss of blood, shock, and exhaustion, eighty-six hours after the injury. At the post-mortem no blood or pus was found in the peritoneal cavity, and the adhesions between the serous surfaces were very slight. There was no pus at the site of the nephrectomy, and the hæmatocele was perfectly aseptic. The ball had grazed the eleventh rib, passed just below the pleura without entering it, had perforated the diaphragm, left kidney, the renal artery and vein, and the sheath of the aorta just at the origin of the renal artery, being found lying directly upon the aorta. The right kidney was healthy.

Case II.—Female, aged thirty-two; tubercular history of ancestry uncertain; failing in health for ten months. Seven weeks ago, first noticed tumor in right side of abdomen. Has had increasing pain in this region. This is now very severe at times. Has emaciated rapidly. Temperature varying from 99° F. in the morning to 101° F. in the evening. Diarrhœa quite constant. Passes large amounts of pus in the urine. Urine one-sixth albuminous, but contains no casts and no distinctive cell-elements. Tumor, rounded in form, occupies the space from the right renal region forward to linea semilunaris, and vertically from lower margin of liver to line of anterior superior spinous process. Indistinct dulness extending into pelvis. Resonance between liver and tumor. Tumor movable.

Diagnosis uncertain. The size of the tumor and its projection forward determined the selection of the abdominal median incision. The right side of abdomen was found filled with thick sac giving indistinct sense of fluctuation. From it extended downward two elongated masses, one evidently a pus-filled ureter, and the other a mass extending down from the external iliac vessels and passing under Poupart's ligament. Puncture evacuated only a few drachms of pus and did not diminish its size. Tearing open the sac, the kidney was found riddled with multiple abscesses. The vessels, and the ureter low down, were tied with silk ligatures and the kidney removed. The abdominal cavity was irrigated with distilled water, drainage-tubes inserted behind the uterus and into the site of the nephrectomy, and the wound closed with one set of sutures. The woman was exceedingly low during the operation, but rallied so that the temperature rose to 99° F., and she became perfectly conscious. Two hours after operation she suddenly sank, and died.

Post-mortem showed that behind the suppurating kidney and in a separate sac, divided from it by a wall two lines in thickness, was another pus-sac. This sac was three inches wide and the pus had worked its way down the aorta, common iliac, and iliac arteries to Poupart's ligament. If nephrotomy had been attempted this sac might have been drained and the kidney never reached at all. No hemorrhage after operation. Death from shock. The other kidney was enlarged but not diseased.

Dr. David W. Cheever, of Boston, read a paper on

SHOCK.

The operative surgery of our time has annulled pain, arrested hemorrhage, averted septic absorption, but it has not prevented shock. The object of the paper was to inquire whether or not modern surgical procedure had diminished shock, wherein it fails to do so, and to suggest improvement of its defects.

In order to diminish shock: 1, Wait for reaction; 2, never neglect to calm the mental shock by a cheerful word and personal presence; 3, give alcohol a quarter of an hour before anæsthetics; 4, make the anæsthesia short; 5, operate as rapidly as possible; 6, as short dressing as possible; 7, avoid chilling of the patient.

To promote reaction after operation: 1, Persistently and carefully applied dry heat; 2, liquid nourishment combined with a stimulant and a little laudanum by enema; 3, subcutaneous injection of brandy; 4, aromatic spirits of ammonia by the mouth; 5, black coffee and brandy, the stimulant par excellence when it can be retained by the stomach; 6, quiet—a more than horizontal position; sleep—assurance that all is over and doing well.

Modern surgery has won three great triumphs: 1, It substitutes sleep for pain; 2, it averts secondary hemorrhage by animal ligature; 3, it prevents fermentation by germicidal applications; 4, can we add a fourth by stilling the nervous system and averting secondary shock?

The paper of Dr. Cheever was followed by a discussion participated in by Drs. Keen, Willard, Bontecou, Prince, Moore, Lange, Weir, and others.

On motion of Dr. B. A. Watson, the Association extended to Dr. Martin a vote of thanks for his labors in bringing about the organization of the Congress of American Physicians and Surgeons, the successful meeting of which was about terminating.

After extending a vote of thanks to the officers, the Association adjourned until the second Tuesday in May, 1889.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNÆCOLOGISTS.

Thursday, September 20th—Third Day.

Dr. Thomas T. Maxwell, of Keokuk, read a paper on

UTERINE FIBROIDS; THEIR DIAGNOSIS AND TREATMENT.

He carefully went over the pathology and causation of the disease, but was unable to throw any new light upon the subject. He thought the diagnosis was often difficult owing to the frequent presence of retro-displacements. The treatment which he recommended was in internal administration of ergot, although he had tried electricity once, but without having proper instruments, and with indifferent results.

Dr. Hampton Eugene Hill, of Saco, Me., reported a case of

OPERATION FOR AN UNUSUAL CASE OF SUBSEROUS UTERINE FIBROID.

The patient was an unmarried woman, aged forty, short in stature, and much emaciated. The tumor was very large for so small a woman. Abdomen had a very firm feeling. The uterus was about normal in size, and slightly movable. There was a soft, fluctuating mass to the left of the uterus, and to the right a firmer-feeling mass, by vaginal examination. The general impression given led to the diagnosis of an ovarian fibro-cyst. The operation was made on January 3, 1888, with the assistance of Drs. J. E. L. Kimball, and F. E. Maxey, of Saco, and Dr. M. C. Lathrop, of Dover, N. H.

All aseptic and antiseptic precautions were observed. Upon making the abdominal incision, the tissues were very vascular. When the tumor was exposed, it was found to be a solid fibroid. The tumor was firmly adherent to most of the abdominal wall, and the adhesions were a net-work of blood-vessels. The hemorrhage was unusually severe. Twelve pairs of hæmostatic forceps were in use before the operation was fairly begun. Then the vessels were secured by ligation and torsion as fast as they were divided; many ligatures were left on the abdominal wall. The omentum was adherent in a vascular mass over the upper part of the tumor. The pedicle was secured by passing an écraseur chain underneath the tumor, and around the pedicle. The lower end of the tumor was then raised, and drawn downward; and then a broad mass of vessels running into the back of the tumor, from the mesentery, was secured by long forceps, and the tumor divided from it. It was then removed from the abdomen, and the mesenteric vessels secured in three ligatures. The pedicle was ligated with strong silk. A cyst of the left ovary, the size of an orange, was then tied and cut off, the abdomen cleansed with hot water, a drainage-tube left in, and the wound closed, dressed, and the patient placed in bed in a collapsed condition. Brandy had been freely injected under the skin during the operation. Drainage was very free during five days; tube removed in six days. There was an accumulation of fluid afterward. Forty ounces were removed on the eighteenth day, after which the patient improved rapidly and made a good recovery. The tumor measured in length sixteen inches, in width fifteen inches, in thickness ten and one-half inches. The weight was forty-seven pounds. The abdominal incision was extended from near the pubes to the ensiforn cartilage.

Dr. Franklin Townsend, of Albany, opened the discussion on

EXTRA-UTERINE FŒTATION,

with a paper on its pathology.

He carefully explained the theories of a great many leading authorities upon the important question as to the place where fecundation takes place. The bulk of authorities think that fecundation takes place in the ovary or in the tube. Wyder, of Berlin, is one of the minority who think that fecundation takes place in the uterus. The reader thought that in a majority of women the fecundated ovum falls into the peritoneal cavity. As a rule the peritoneal soil is not suitable for the growth of the fecundated ovum, and it dies. In rare cases the peritoneal soil does suffice to nourish the ovum and then we will have peritoneal fœtation. In other cases the impregnated ovum is caught or arrested in the Fallopian tube, which becomes enormously developed in muscle. Sometimes the tube ruptures near the placental site, when severe hemorrhage occurs and the woman dies from shock or from peritonitis. In other cases the fœtation goes on to full term, and is removed either whole, or it dies and the bones are discharged through the rectum or vagina. Many cases have been recorded of ovarian fœtation, where the ovum never leaves the ovary. He then described the conditions of abdominal or peritoneal pregnancy. He then showed a specimen of extra-uterine fœtation which had lain quiet in a woman fifty years, without causing any inconvenience after the first few weeks succeeding the end of the natural period of pregnancy.

Dr. Joseph Price, of Philadelphia, then read a paper on the

DIAGNOSIS OF EXTRA-UTERINE FŒTATION.

Cessation of menstruation not constant. Sickening pelvic pain due to distention of the tube. The discharge from the uterus is not like the usual menstrual discharge, being thinner and lighter in color. He agreed with Mr. Tait that all extra-uterine fœtations were primarily tubal. The diagnosis was certainly difficult. When the fœtus died before the bursting of the tube diagnosis was almost impossible. When the tumor increases the pressure-symptoms are more marked. The rupture may take place into the abdominal cavity or downward, between the layers of the broad ligament, into the pelvis. One pathologist had found eighteen cases of ruptured tubal pregnancy where the cause had not been diagnosed.

The patient may die at the moment, or she may recover from each recurring hemorrhage. When the rupture takes place into the pelvis she genrally becomes a chronic invalid with pelvic abscess.

A diagnostic sign is the unilateral condition of the swelling. The fœtal sounds are exaggerated. Digital examination is essential. The uterus is enlarged, but not nearly so much as in normal pregancy. If she carries the extra-uterine fœtation to term a spurious labor ensues, with a sort of lochial discharge, and then the fœtus is disposed of by nature in various ways.

Dr. E. E. Montgomery, of Philadelphia, read a paper on the

TREATMENT OF EXTRA-UTERINE FŒTATION.

As a rule the patient dies from shock at the first rupture, or else from hemorrhage. In many cases, however, the patient recovers, the blood and fœtus becoming encysted. He believed that electricity offered the best chances of success. It was known that mice placed in a vessel of water could be killed by passing an interrupted current through it. It was easy, free from danger, and was almost certain to put an end to the condition. After four months its use was more doubtful, because it would be better to remove such a large foreign body; we might, however, use faradic electricity for killing the fœtus so as to cause coagulation of the blood in the vessels before operating a few weeks later. He thought that Martin's plan was the best for dealing with the placenta; that is, to make a hole through Douglas' cul-de-sac and pass the cord through it, closing up the abdominal opening of the ruptured sac.

Dr. Walthen, of Louisville, rather sided with Mr. Tait in holding that all extra-uterine fœtations were primarily tubal. He did not believe that an impregnated or any other ovule could form an adhesion to the peritoneal surface. He thought that any pathological condition of the tubes or pelvic organs which would interfere with free movements of the tubes, would lead to retention of the ovule in the tube.

Dr. Baldy, of Philadelphia, said that the differential diagnosis of this condition was simply impossible, unless made inside the abdominal cavity. He related several cases where intra-uterine pregnancy had been diagnosed and when the fœtus was supposed to have been killed by electricity, and where afterward the disease was found to be either an ovarian cyst or a pyo-salpinx. He thought no treatment was so safe or so satisfactory as laparotomy.

In conclusion, he recommended the following plans of procedure:

1. In every form of ectopic gestation, prior to the fourth month, the destruction of life by electricity (faradic current).
2. Between the fourth and sixth months, destruction of life by electricity, and some weeks later laparotomy.
3. In rupture, immediate laparotomy, with removal of sac, contents, and the effused blood.
4. In cases that have passed the sixth month, wait until viability is well established, and perform laparotomy, observing every precaution that separation of the placenta does not occur; close the sac above, or down through the vagina.
5. In case of death of fœtus, it should be removed by laparotomy a few weeks later.
6. Where the fœtus has become macerated and abscess has formed, its sinus should be enlarged, and the fœtal residuum removed.

Dr. Byford, of Chicago, thought that these cases could be diagnosed, although he admitted that the diagnosis was difficult. He related a case where he was about to operate, but having delayed a few days the symptoms began to disappear and the woman finally quite recovered. He counselled delay if the symptoms were not urgent. He was in favor of electricity.

DR. MCMURTRY, of Kentucky, thought the differential diagnosis was impossible before opening the abdomen. He related a case where he had operated, and where the placenta was so enormous and so adherent that when he attempted to remove it the hemorrhage was frightful, and the woman died next day. In future, he would leave the placenta there and drain through the vagina.

DR. JOHN B. DENNER, of Philadelphia, thought that every case of abdominal surgery should be irrigated with hot water, as it stimulated the sympathetic and avoided shock, to say nothing of increased cleanliness. In case of intestinal obstruction, he urged reopening the abdomen. He had no confidence in electricity for this purpose.

DR. VANDER VEER, of Albany, read a paper on the same subject. He thought the diagnosis was in many cases possible. The electrical treatment was advocated before the fourth month. The faradic current was preferable. Galvanic puncture had generally been fatal. Only one case of death had followed the application of the faradic current. The electrical treatment does not give a radical cure as removal by laparotomy. Martin advocated immediate removal as soon as diagnosed. He reported a number of cases which all showed that this was the best treatment, for when left alone, although the woman ultimately recovered, yet they passed through several months or years of severe suffering.

This closed the discussion, which was listened to throughout with the most marked attention, showing that, as several speakers remarked, the subject was becoming familiar to the mass of practitioners, a most desirable consummation, in view of the importance of early diagnosis.

DR. GEORGE ROHÉ, of Baltimore, read a paper on

SOME COMMON DISEASES OF THE SKIN ASSOCIATED WITH GENERAL DISORDERS IN THE FEMALE.

These were urticaria, hyperidrosis, and acnea. He found arsenic very effective in treating them. Chloasma may be removed with one drachm of nitrate of bismuth and one drachm of ammoniate of mercury to the ounce of vaseline. Pruritus could only be cured by removing the cause of the irritation, which in one case was due to smegma retained beneath the prepuce of the clitoris.

DR. EDWARD J. ILL, of Newark, N. J., read a paper on

DERMOID (FIBROID) TUMOR OF THE ABDOMINAL WALL.

This is a somewhat rare disease. It measures thirteen centimetres in length and seventeen in breadth. When it was removed there remained a large opening in the abdominal wall, which was closed by a very large number of sutures, and which healed by first intention. During the operation the stomach, liver, and intestines were exposed. In future, the operator would remove the adherent peritoneum. There was very severe hemorrhage from the capsule of the tumor, but very little from the growth itself, which is very hard and dry. The diagnosis can sometimes only be made under ether. The paper was illustrated with diagrams.

DR. LAPTHORN SMITH, of Montreal, then read a paper on

SOME MINUTE BUT IMPORTANT DETAILS IN THE MANAGEMENT OF THE CONTINUOUS CURRENT IN GYNECOLOGY.

He said that one of the most attractive features of this method was its absolute safety, but at the same time he pointed out that it was only absolutely safe on condition that rigorous antiseptic precautions were taken. He recommended a corrosive sublimate injection, before and after every application, and the placing of an iodoform tampon in the vagina to prevent coitus. He then showed a form of electrode for the abdomen which was superior to Apostoli's and equal to Martin's, but which any physician could make for himself at a nominal cost. He advocated the use of Martin's intrauterine electrode for positive applications, while any form of silver-plated sound would do for the negative applications. For making positive punctures, he said that platinum alone would do, but he thought they were rarely required as the hemorrhage could be controlled easily by means of the positive intra-uterine applications, and then the growth could be arrested and reduced by the negative galvano-puncture. He recommended that punctures should be dispensed with as much as possible, as they were somewhat dangerous, and very good results could be obtained with intra-uterine applications, provided that the two poles were so placed as to bring the growth entirely between them. If the growth were situated in the posterior segment of the uterus, the inactive pole should be placed on the sacrum. The reader of the paper referred to several cases under treatment, in which he had first removed the anterior half of the growth and then the posterior half by this means, and without puncture. He recommended Gaiffe's galvanometer, which was more reliable than any so far made in America, and he pointed out the sources of error in galvanometers. In speaking of the battery, he was strongly in favor of Leclanché's conglomerate cell, owing to its splendid depolarizing qualities; next to that he thought the old Leclanché cell, with porous pot, was the best for steady work. The climbing of the salt could be avoided by well waxing the tops of the jars or having them sealed. He found the Law telephone cell unsuited, owing to its rapidly polarizing, and thus allowing the current to run down. He was not in favor of Gaiffe's collector used by Apostoli, but preferred a Bailey rheostat, by which the strength of the current could be finely adjusted.

With regard to the after-care of the patient, he thought it was very desirable that she should be put to bed immediately after a puncture and be kept there for at least a day. After application at the office, he advised that the patient be allowed to lie on a sofa for at least half an hour afterward, or even longer. The counter-indications were pregnancy, which should be carefully looked for in every case, and any tendency to acute peritonitis and cellulitis, as these conditions were apt to be relighted up by the continuous current. The only accidents he had had after a year's constant use, during which time he had made nearly one thousand applications, was one abortion, and one resetting up of pelvic cellulitis which had resulted in abscess of the broad ligament, from which, however, the patient had recovered. The results in fibroids had been: 1, That in every case bleeding had been arrested; 2, that pain had been removed; 3, that the symptoms of pressure on the bladder and rectum had ceased. In one case, a lady had been confined to her bed for eight days every month for the last twenty years, but after three months' treatment she had passed through a period of normal length and quantity absolutely free from pain. In another case, the canal was so blocked up when he began treatment that no kind of bougie, flexible or otherwise, could be got in, and it required six negative applications before the sound could be introduced into the fundus six inches. After that it passed with the greatest facility, and although she had suffered agony every month for eight years previously, she now menstruated almost without knowing it. He admitted that the treatment was tedious in fibroids, and was only worth the trouble on account of the danger of operative procedure.

He then spoke of the value of the continuous current in dysmenorrhœa without fibroid, in cases of stenosis of the uterine os, in which he recommended the passing of a series of silver-plated graduated bulb-electrodes by means of which the canal could so be brought up to any size. He cited several cases of severe dysmenorrhœa which had been permanently cured by this method.

A number of papers were then read by title, owing to the absence of the readers, and the next meeting-place was announced for Cincinnati, at about the same date next year. A large number of applications for membership were referred to the committee.

The Association then adjourned.

AMERICAN GYNECOLOGICAL SOCIETY.

THURSDAY, SEPTEMBER 20TH—THIRD DAY.

Dr. T. A. Reanny, of Cincinnati, read a paper on

AMPUTATION OF THE CERVIX UTERI FOR CARCINOMA.

His paper covered the statistics of ten years' work from 1876 to 1886. About three hundred cases were seen by him during this period in hospital, private, and private hospital practice. He selected fifty-five of these cases as favorable for operation, the disease not having extended from the cervix, and in which he thought he could remove all the disease. These cases were the basis of his report Medical treatment he considered amounted to nothing. Surgical treatment, if resorted to early, may save some; hence this is the only treatment. If employed early in cancer uteri, removal may prove successful. The importance of early diagnosis and operation need not be dwelt upon. He had been on duty at the Good Samaritan Hospital for eighteen years, and the number of cases which came to him there in the earlier stage was very small. They do not come there till far advanced. It is his belief, after considerable experience, that the diseased tissues can be more thoroughly removed by amputation of the cervix than by total extirpation. The parts posterior are removed more extensively, and these are the dangerous tissues. In total extirpation we do not cut so freely, more attention being given to the operation for the removal of the uterus. Twenty-nine of the fifty-five cases recovered. No recurrence in twenty-six cases. One case recurred after three years, which goes to show that the claim that the patient is cured if there be no return for three years, is not so.

The paper was discussed by Drs. Baker, Boston; Brun, Brooklyn; Emmet, New York; Vander Warker, Syracuse.

Dr. Graily Hewitt, of London, read a paper on

SEVERE VOMITING IN PREGNANCY.

He did not believe in the old saying, a sick pregnancy a safe one. He enumerated as causes: emotion, chronic alcohol, alteration in the position and shape of the uterus. To the latter he devoted his particular attention. He exhibited a large printed table which went very thoroughly into the subject. In cases of anteversion of uterus with impaction, the trouble was a very stubborn one. He mentioned cases where the pessaries were introduced and the vomiting relieved. They were removed, and the vomiting returned.

Dr. Fordyce Barker and Dr. Skeene, of New York, discussed the paper at length.

Papers were also read by Drs. C. M. Green, of Boston, on "A Case of Rupture of the Uterus in Labor at Term, the child born alive, the mother subsequently having a full-term child in normal labor;" and one by Dr. Polk, of New York, on "The Treatment of Pelvic Cellulitis."

The election of officers resulted as follows: *President*, Dr. H. P. C. Wilson, of Baltimore; *First Vice-President*, Dr. William Thompson Lusk, of New York; *Second Vice-President*, Dr. E. W. Jenks, of Detroit; *Secretary*, Dr. Joseph Taber Johnson, of Washington; *Treasurer*, Dr. Matthew D. Mann, of Buffalo; *Members of Council*, Drs. J. E. Janvrin, of New York; A. H. Baker, of Boston; C. R. Dryesdale, of Philadelphia; Ely Vander Warker, of Syracuse.

The next place of meeting was selected to be Boston, time, Tuesday, September 17, 1889.

"The Dangers of Galvano-Puncture in Pelvic Tumors" was an interesting paper, by Dr. Ely Vander Warker, of Syracuse, N. Y. "The Infertility of Women; some of its Causes and Requirements of Treatment," by Henry F. Campbell, of Augusta, Ga. "A Case of Subinvolution cured by Removal of the Appendages," was reported by Howard A. Kelly, of Philadelphia.

Dr. George J. Englemann, of St. Louis, read a paper entitled

THE NEW METHOD OF ELECTRO-THERAPY IN GYNECOLOGY.

He had not attained that success which had been the fortune of Apostoli, the Keiths, and Dr. Baker, but his success had been all that we could justly expect. He spoke more extensively of galvanism as an adjuvant for surgery. He did not think surgery should be supplanted by electricity. A very important factor in certain classes in the electrical treatment was the ability of the patient to go about and attend to the usual duties of life. If a final result to the knife is necessary, the electricity has put the patient in a better condition. Indurations, inflammatory products, interstitial inflammations, and neoplasms are proper subjects for this treatment. He thinks a trial should be made of electro-therapeutics before operation is resorted to. After a very few sittings we are able to decide whether we can proceed with benefit or not. He reported several cases from the Berlin clinic. One thing greatly in favor of the treatment is the favor by which it is held in the opinion of men known to be strongly in favor of surgery, viz., Keith and Martin.

Dr. H. P. C. Wilson, of Baltimore, thought that our success depended on the selection of suitable cases. Not all cases are suitable for electricity. Reported his experience in the clinic of Apostoli. In many gynecological cases, heretofore considered incurable, we will find this treatment productive of much good.

Dr. Graily Hewitt had not had much experience, but thought the electrical treatment would do much good.

Dr. Parrish, of Philadelphia, said that it was well known that the most favorable results obtained by electricity is in the treatment of pelvic exudations. He thinks in these cases there was no suppuration. He questions if there was pus, electricity would harm by delay if not otherwise.

Dr. Gill Wylie, of New York, showed some instruments for the high operation of Cæsarian section.

Dr. H. T. Hanks, of New York, read a paper on

THE EARLY DIAGNOSIS OF TUBAL PREGNANCY AND ITS TREATMENT BY ELECTRICITY,

with a report of two successful cases. The doctor thought that if the diagnosis was made previous to the fourth month the treatment should be electricity, if after the fourth month laparotomy. He lost 2 cases out of 16 after laparotomy, and 2 out of 20 after electricity.

Dr. Matthew D. Mann, of Buffalo, read a paper entitled "The Varieties of Extra-uterine Pregnancy," Dr. J. E. Janvrin one on "The Treatment of Extra-uterine Pregnancy," and Dr. B. F. Baer, of Philadelphia, on "A Case of Extra-uterine Pregnancy."

Dr. Clark, of Calcutta, said that his experience had been limited. It was difficult to gain the consent of the people in India to this operation. He thought the work of American men had proved that electricity could do very much in these cases.

Dr. J. C. Reeves, of Dayton, Ohio, knew of no other subject in gynecology to which this society had added so much. The doctor had reported four cases to this society and every time he had been told that his diagnosis was faulty. Treatment seems to be yet an unsettled question, arguments are presented for and against electricity and laparotomy; we have not yet had experience enough with the destruction of the fetus to feel sure that any bad results cannot occur from the use of electricity from the remaining sac, no man can have a large experience in extra uterine pregnancy, and one thing in favor of the application of electricity is its adaptability to the use of the general practitioner more than is laparotomy. I always have my instruments ready for laparotomy with me when applying electricity, for I think electricity may cause that which it is used to prevent, viz.: the rupture of the sac.

Dr. S. C. Gordon, of Portland, Me., reported a case on which he had operated.

Dr. J. W. Johnstone, of Danville, Ky., believed in the knife and condemned the electricity.

Dr. Englemann, of St Louis, and Dr. Polk, of New York, continued the discussion.

Several papers were read by title and the Society then adjourned.

ASSOCIATION OF GENITO-URINARY SURGEONS.

Thursday, September 20th—Third Day.

It was voted that the next meeting of the Association should be held at Newport, R. I., in May next, but that the day be left to the future decision of the Council.

Dr. William H. Kingston, of Montreal, read a paper entitled

OPERATIONS ON THE KIDNEY.

Operations on the kidney are of recent date. The French were the first to bring attention to this subject, the author the first to operate in America. The operation is now established as a proper one in suitable cases. What are suitable cases? It is difficult to determine in each particular case from the usual circumstances of uncertain diagnosis, as proved by numerous citations by the author of mistakes by many of the most celebrated surgeons of Europe and America. The author mentioned, as an illustration, a case of his in a female, in which he was unable to determine with certainty whether the tumor was of the ovary or connected with the kidney. Operation showed it to be a cystic tumor of the kidney. There was in this case a certain clearness of resonance on percussion at the left of the umbilicus, which led the author to strongly incline to this diagnosis, as this quality of percussion-note is rarely present in ovarian cyst, and is a sign of kidney cyst. The tumor was of the size of the gravid uterus at full term of gestation. The severing and ligation of many vessels, with the difficult ligation of the pedicle, protracted the operation to over three hours, and the patient died from the shock.

The author raised the question of division of as many ribs as may be necessary to render the removal of the tumor easy when the "post-peritoneal" operation is performed, which he employs.

Dr. Frank W. Rockwell reported a case of

NEPHRO-LITHIASIS, COMPLICATED WITH HYDRO-NEPHROSIS,

in which lumbar nephrotomy was performed. Discussion of the preceding paper was postponed until after the reading. Dr. Rockwell, the author, remarked that in one-half the cases so far reported there had been failures to find the stone. The case was that of a man who had passed a calculus as a boy, and within the last few years has had a return of his symptoms. All other treatment failing, a lumbar incision was made, December 29th, thorough exploration of the kidney was made, but the calculus escaped detection. During the next twenty days intermitting discharge of limpid fluid from the wound continued. This now ceased and a small fragment of calculus was passed, the symptoms ceased, and the patient went South. Symptoms of vesical calculus again presented, and on March 17th another and larger fragment came away and the patient recovered. The symptoms of pyelitis and hydro-nephrosis still remain, and the patient was still under observation.

Dr. Charles T. Park, of Chicago, showed a large calculus removed from the left renal pelvis of a patient upon whom he operated by the lumbar route. The symptoms were intermittent attacks of pain in the region of the left kidney, accompanied with discharges of purulent urine. The patient speedily recovered after the operation, and was relieved of his symptoms.

Sir William MacCormac, of London, narrated several interesting and instructive cases bearing on the subject. One was a young man on whom he operated by abdominal incision for supposed stone lodged in one ureter. The ureter was explored through its whole length, but no stone could be found. The patient recovered, and afterward was accepted as a recruit in the English army.

Dr. Lange, of New York, had only performed the lumbar operation. The dread of septic infection deters him from the abdominal incision when there is pus. The speaker described the difficulties encountered in removing fragments of stone when they become snared in the calices of the renal pelvis, and advised, for this reason, care in extracting the stone as a whole.

Dr. W. Gill Wylie, of New York, advocated the anterior operation, because of the greater freedom for action it presented. He had not found it extraordinarily dangerous, and related a case of a woman of seventy who recovered perfectly after removal, by this route, of a renal cyst, involving great difficulties, and in which calculi were found with considerable pus in the pelvis and ureter, and removed.

Dr. Weir, of New York, criticised the abdominal incision as an unnecessary opening of the abdominal cavity for a purpose which could be attained in most cases just as well by the lumbar incision, but he would emphasize the importance of making the incision very free in whatever direction the incisions were made.

Professor Annandale, of Edinburgh, took the same view. He had practised the posterior operation only. The incision could be made large enough to give all the freedom of action required in most cases.

In conclusion, **Dr. Rockwell** said, that it appeared from the discussion which his paper had called out, and which had taken a wide range and was a very complete expression of current views on the subject, that the indications for the operation were pretty well established, and that the posterior operation should always be employed when possible to use it successfully, and that the anterior should be reserved for only those cases where the tumor promises to be too large to remove by the other route, or in which, for any other reason, it was impracticable.

Dr. George Chismore, of San Francisco, Cal., read a paper entitled

EFFECTS OF RAPID CHANGE OF ALTITUDE IN A CASE OF INTERSTITIAL NEPHRITIS IN AN ADVANCED STAGE.

The author remarked that he had been unable to find any reference in medical literature on the points brought out by his case, and that it is important to bring attention to it. The history of the case was carefully given, and an account of the journey from San Francisco to New York, in which the reader accompanied the patient. From this the ill effects of rapid changes of altitude on the symptoms were well brought out, the patient having died soon after his arrival in New York. An autopsy confirmed the diagnosis. The conclusion reached by the author was that he would strongly urge persons suffering from renal disease of the diffuse type, with heart complications, to avoid all journeys involving great and rapid changes in altitude.

Dr. Fessenden N. Otis, of New York, read a paper entitled

RESUMÉ OF AN EXPERIENCE OF SEVENTEEN YEARS IN DILATING URETHROTOMY FOR THE RADICAL CURE OF STRICTURE.

The author remarked upon :

1. The necessity of acquiring knowledge of the nor-

mal urethral calibre before any operative measures were instituted, and then of the exact locality and size of every stricture in a presenting urethra.

2. That there should be an accurate adaptation of surgical procedures to the individual strictures, with intent to remove them through complete sundering at some one point.

3. Claiming this to result when the division had been completely effected by the complete absorption of the stricture so divided.

4. Claiming, further, greatly diminished total risk of operative measures as compared with attempts at more or less complete removal of stricture by any other method. He then referred to his first report of one hundred tabulated cases, comprising two hundred and fifty-eight strictures, where no deaths or grave accidents had occurred, and that in thirty-one cases re-examined—two over three years, twenty-three over one year after operation—freedom from any trace of stricture was demonstrated. From this fact the possibility of radical cure of stricture was then asserted.

Dr. Otis then referred to improvements made in the instruments up to the present date, and the wide spread of the operation, and dilated upon the complete division of stricture, always on the superior surface and in the median line, and claimed that failure to produce a permanent result was due chiefly, if not entirely, to a failure to secure these requirements.

A second series of one hundred and thirty-six tabulated cases was presented, and eighty-two re-examinations reported; recontraction occurred in sixty-seven cases, the intervals being in two cases over five years, in three over four years, in ten over three years, etc.

During the present summer he had had tabulated a third series of four hundred and twenty cases, with results of re-examination in sixty-two cases, in which recontraction had taken place in eighteen cases, the remainder being entirely free from all trace of stricture. Dr. Otis then referred to the first case operated on by him by the dilating urethrotome (in May, 1871), which he re-examined in May last (1888), seventeen years from the date of operation, and found absolute freedom from all trace of stricture, proving completely its radical cure.

Dr. Hingston, of Montreal, did not believe that there is any uniformly fixed relation between the size of the normal urethra and the circumference of the penis. He had not always, but generally had gotten permanent results by Dr. Otis' method of dilating urethrotomy in a class of cases in which formerly the rule had been failure. He took exception to the theory that the passage of urine over the wounded urethra is the cause of urethral fever.

Dr. Otis, in answer, said that he thought he could convince Dr. Hingston in regard to relative size of the urethra and penis, if he would accompany him in the examination of a number of normal urethræ.

Mr. Charles Williams, of Norwich, England, presented a paper (by invitation) on

STONE IN THE BLADDER IN CONNECTION WITH SPLENIC LEUKÆMIA.

The case illustrated the rapid accumulation of uric acid crystals, in connection with splenic leukæmia. Other cases were related by the author, of a similar nature, on eminent authority.

Mr. Reginald Harrison, of Liverpool, read a paper entitled

PERINEAL LITHOTRITY.

The great advantage that lithotomy possesses over lithotrity is that it permits the operator to ascertain the condition of the bladder and prostate, and to satisfy himself that every particle of the stone is removed. Thus relapses are explained as more frequent of lithotrity. He gave statistics to support his position. The author expressed the opinion that if the advantages of litholapaxy could be combined with those of lithotomy, so far as the latter applies to exploration of the bladder by the finger, that much advantage would follow in certain cases, in which recurrence after lithotrity might almost with certainty be anticipated. For this purpose perineal litholapaxy seemed to be well suited, securing, first, digital exploration; second, rapid evacuation; and third, drainage. This could be accomplished without encroaching upon the neck of the bladder. Gouley, in 1873, mentions such a procedure.

The author has employed a modification of this operation in four cases. In three the prostate was large and drainage was important; in two of them litholapaxy had previously been performed; in the fourth case the stone was very large. The patient was eighteen years of age, and the stone phosphatic, and was thought to be proper for litholapaxy. The stone was seized and crushed by the lithotrite, but as the blades could not be approximated sufficiently to allow the locking of the instrument, perineal lithotrity was proceeded with. The membranous urethra was opened and the finger passed into the bladder, the stone found being large as supposed. A strong pair of forceps were introduced into the bladder, with which the stone was crushed and extracted. The finger showed that the bladder was free; the latter was washed out with a bichloride solution, and a large drainage-tube inserted and kept in four days and then withdrawn. The patient was well, and up on the eleventh day, passing urine by the urethra. Though the stone weighed three ounces it was broken up and removed in five minutes. The other three cases were dealt with similarly. In conclusion the author thought that perineal litholapaxy would be found of considerable advantage, and would tend by its use to lessen the number of recurrences which follow litholapaxy.

Discussion: Dr. Bryson remarked that he had already mentioned before the Association three cases in which he performed the same operation and for the same indications as described by the author of the paper. Dr. Keyes had also performed the operation. A distinction was to be made between perineal lithotrity and perineal litholapaxy. In the former, the neck of the bladder being dilated rendered the latter impossible, where the stone was small the latter was easily successful, or by reducing a larger stone to sufficiently small fragments.

Dr. Henry G. Mudd, of St. Louis, reported

AN UNUSUAL CASE OF URETHRAL CALCULUS.

The interesting feature was the large size and location of the calculi. The largest (two hundred and eighty-one grains) was situated in front of the bulb, and seven or eight smaller ones in the membranous portion of the urethra. Several small stones were found in the bladder lying in pockets. The urine had been forced around the stones in the urethra, and the author thought the stone was small when it first found its way into the urethra and received accumulations by the urine passing about it. It had existed for years, at least, in the position from which it was removed.

Dr. Arthur T. Cabot, of Boston, reported a case in which the bowel ended in the urethra of a child four weeks old. Relief was obtained by operation.

Dr. J. Nevins Hyde, of Chicago, presented a paper on "Syphiloma of the Vulva."

The President, Dr. Keyes, then vacated the chair with appropriate words, and called upon Dr. Taylor to assume the presidency of the Association, to which he had been elected for the ensuing year.

The Association then adjourned.

A Confusion of Names.—A young physician, by the name of Macewen, has recently died in Glasgow, and several of the Paris and Vienna papers, misled by the name, have published more or less elaborate obituary notices of the well-known surgeon, Mr. William Macewen.

AMERICAN NEUROLOGICAL ASSOCIATION.

Thursday, September 20th—Third Day.

Dr. G. L. Walton, of Boston, presented a paper on

DISLOCATION OF THE CERVICAL VERTEBRÆ,

relating two cases in which there was spontaneous recovery, and giving histories of several other similar injuries.

In the discussion which followed **Dr. Webber** reported the case of a stout man who fell from a chair, upon his shoulder, thus giving his head a severe jerk. He was picked up paralyzed in both legs and partly in both arms. In thirty-six hours the paralysis of the legs began to improve, and passed off altogether within a few days. The arms recovered imperfectly, and he suffered intense pain in them, for which morphia was given for months. This was probably the cause of the constant nausea present. He believed that there was a dislocation of the cervical vertebræ in this case, with spontaneous recovery.

Dr. L. C. Gray referred to a case of dislocation of the third cervical vertebra, which he had reported eight years ago. A young boy fell down a flight of stairs. There was paralysis of the upper and paresis of the lower extremities, and difficult deglutition. It was reduced under ether, and in a week the boy was well. He then had the misfortune to fall in the same manner and again dislocate his neck. It was again returned to its place, and he was perfectly well when last seen, one year after the accident.

Dr. James J. Putnam thought that the permanent atrophy in one of Dr. Walton's cases might be explained by mechanical injury or hemorrhage in one of the nerves at the point of origin.

Dr. Walton had been very uncertain as to the cause of this, but had believed it due to compression.

Dr. Bannister, of Kankakee, gave the details of a case, with atrophy of the arm and tongue, following a cervical pachymeningitis.

Dr. E. D. Fisher also reported a case of dislocation of the neck, occurring many years ago in one of his patients, an old woman, who had permanent paraplegia and wasting of the arms.

Dr. Landon C. Gray, of New York, then reported upon a case with

TYPICAL SYMPTOMS OF DISSEMINATED SCLEROSIS, THE POST-MORTEM EXAMINATION REVEALING ONLY LEPTOMENINGITIS.

This patient was under observation for three years. He had intention tremor, nystagmus, scanning utterance, exaggerated patellar reflexes, and later apoplectiform attacks, violent emesis at times, and increasing dementia. There were no sensory disturbances, no neuro-retinitis or other changes in the cranial nerves. The autopsy showed leptomeningitis diffused over the convexity of the cerebrum. Careful search failed to discover any sclerotic patch in cerebrum or cerebellum. There were peculiar varicosities in the cerebral nerve-fibres. A case similar to this had been described by König, of Berlin, last year.

Dr. Webber remarked that epileptiform seizures were very rare in typical disseminated sclerosis.

Dr. Bannister thought the case one of general paresis where a meningo-encephalitis is common.

Dr. Fisher mentioned a case of his of general paresis where there were epileptiform seizures and an intention tremor.

Dr. Gray said that in his case the attacks were apoplectiform with rise of temperature.

Dr. C. K. Mills stated that the symptoms in such cases were due to the localization and not to the nature of the lesion. The tremor was caused by want of normal relation between the motor impulses and conduction. Sclerosis might exist in many portions of the nervous system without producing tremor, but in certain places it will always do so. A leptomeningitis over the motor areas would be apt to give rise to tremor. Leptomeningitis is very common in general paralysis.

Dr. Blackburn, of the Government Insane Asylum, Washington, then exhibited, by invitation, some preparations of brain by an original method. A brain, or any part of it, is first hardened by any of the current methods, such as chrome salt solutions, alcohol, or chloride of zinc, then dehydrated thoroughly in alcohol, and subsequently placed for three days in a saturated solution of Japanese wax in chloroform. This wax is a concrete oil obtained from a Japanese tree. The specimen is then placed for three days longer in melted Japanese wax, kept in a molten state over a water-bath. It may then be removed, drained, and allowed to dry. It now suffers no change from exposure to the atmosphere, and may be used for demonstration of the coarser morphology, and perhaps even of the finer. Some of the specimens presented had been in service for two years.

Dr. S. Weir Mitchell, of Philadelphia, read a paper on

ANEURISM OF AN ANOMALOUS ARTERY, CAUSING ANTERO-POSTERIOR DIVISION OF THE OPTIC CHIASM AND BI-TEMPORAL HEMIANOPSIA,

which was read by **Dr. F. X. Dercum**. The case had been seen by the author six months before death. The color-sense was normal. There were no changes in the fundus, and no mental disturbance. The patient died suddenly. The aneurism was formed by the two carotids, was the size of a lemon, and lay in the eroded cavity of the sella turcica. The anterior communicating artery was absent, otherwise the circle of Willis was normal.

Dr. Frederick Peterson, of New York, presented a paper entitled

A CONTRIBUTION TO THE STUDY OF MUSCULAR TREMOR.

The author exhibited some fifty myographic tracings of various tremors taken with the Edwards' sphygmograph. The myograms were from the supinators and pronators, the carpal extensors, interossei, and head in paralysis agitans, and from cases of multiple sclerosis, delirium tremens, neurasthenia, alcoholism, morbus Basedowii, and hysteria. He found the rate of oscillation to be from 3.7 to 5.8 per second in paralysis agitans; from 4.6 to 6.3 in multiple sclerosis; 8.7 to 12, in exophthalmic goitre; 7.6 to 7.8 in hysterical tremor; 8.5 to 11.2 in alcoholism; about 7.4 in neurasthenia, and from 5.6 to 6.8 per second in delirium tremens. The rapid tremors correspond almost exactly with the normal innervation rhythm of ten per second, while the slower tremors are the result of fusion of two or more motor impulses from the cortex. He also presented tracings of ankle clonus from a case of lateral sclerosis, the rhythm of which was six per second. The pathology of tremor was discussed, and a short review of the literature of myographic study given.

Dr. Sinkler asked if the author had ever attempted to get tracings of the ankle and knee clonus, when both were present, to determine whether they were synchronous or not.

Dr. Peterson said that he had not.

Dr. Putnam stated that he had made curves of ankle clonus at one time by means of a myographic apparatus devised by himself.

Dr. Dercum asked for particulars as to the mode of application of the instrument when obtaining tracings.

Dr. Peterson explained the difficulties in the way of making the myograms, because of the intentional characters of many of the tremors, and the fact of their being developed only when the fingers or hands are extended. He generally seats the patient and himself, with the arms of the patient against a table, and his own elbows upon some fixed support. But none of the obstacles alter the rate of vibration or materially change the peculiar characteristics of certain tremors.

Dr. Hare described at some length a kymographion devised by a Philadelphia mechanician under the supervision of Dr. Weir Mitchell, some years ago, for the study of ankle-clonus and other muscular movements.

Dr. Philip C. Knapp, of Boston, detailed the histories of three cases exhibiting certain

POST-HEMIPLEGIC DISTURBANCES OF MOTION IN CHILDREN,

after which **Dr. J. H. Lloyd**, of Philadelphia, communicated the report of

A CASE OF TUMOR OF THE CERVICAL SPINE.

The patient died three days after the operation. The surgical report of the case was presented by **Dr. John B. Deaver**, of Philadelphia. At the autopsy there was found a condition of ostitis in the vertebra and some pachymeningitis.

Dr. E. O. Shakespeare, who had made a microscopic examination of the cord, reported to the Association the result of his investigation. On the anterior portion of the cord was a small protrusion about the size of a grain of wheat. The chief lesion was hemorrhagic extravasation with slight focal myelitis in this portion of the cord.

Dr. C. K. Mills thought there would be great difficulty in making a differential diagnosis between such a lesion and one higher up, as the symptoms would necessarily be so much alike. The local pain was no doubt due to the local inflammation in the membranes. The complete paralysis of arm and leg in this case, with the absence of facial paralysis, would assist materially in the diagnosis. The case was one of physiological importance, because the lesion had been so well studied clinically and pathologically. As to operating in such cases, the question for the neurologist to decide is not only as to the safety of opening the membranes, but also as to whether the lesion can be reached by operating.

Dr. Dercum desired to know what relation there was between the lesion in the cord and the ostitis. There seemed to be in the report no apparent connection between the two.

Dr. Putnam inquired if there was any extinguishment of pain or temperature sense, because he saw the lesion extend through the antero-lateral portion of the cord.

Dr. Lloyd, in closing the discussion, said that the case seemed much like one of ordinary hemiplegia, and had, in fact, been sent to his ward as such. It was several days after that he discovered the swelling in the back of the neck. He then studied the case carefully and made the diagnosis of a tumor compressing one side of the cord. The gradual onset of the disease seemed to point almost conclusively to that. There was no tactile anæsthesia on the sound side. He had not especially tested the pain and temperature senses, but knew that the patient felt pinching and warmth. The lesion was too far above the cervical enlargement to affect the trophic centres of the arm. All of the nervous system above the lesion was normal. He had no particular theory to account for the ostitis, pachymeningitis, and the hemorrhagic extravasation with myelitis, but surmised that there was primarily disease of bone, due, probably, to injury, and that the ostitis extended, by contiguity of tissue, to the meninges and cord. The operation had been sanctioned by Dr. D. Hayes Agnew.

Dr. Putnam asked if the nerve-roots had been examined with reference to sclerotic processes, and was answered in the negative.

Dr. Wharton Sinkler, of Philadelphia, then read a paper on

HEREDITARY CHOREA.

He gave a general review of the literature of the subject, and added the histories of two choreic families which had come under his observation. He reached three conclusions as to this form of chorea: First, that it is hereditary; second, that it generally becomes manifest between the ages of thirty and forty; and, lastly, that it is as a rule incurable, and there are concomitant mental changes tending toward dementia.

Dr. Knapp reported a case having many symptoms in common with hereditary chorea.

Dr. Mills stated that he, also, had seen recently a case of Huntington's chorea—a woman whose father, and young daughter, a few years old, were all affected similarly.

Dr. Gay, of London, in allusion to the derivation of the term "megrims" used by common people to designate this disease, said that there is a choreic disease in horses, which in England is called the megrims.

Dr. Brush stated that among the people of the lower classes in Connecticut and Long Island, the term "megrims" was applied to drunkenness or any similar condition in men.

The names of Dr. David Ferrier and Mr. Victor Horsley were proposed for honorary membership in the Association, and the meeting was adjourned.

AMERICAN DERMATOLOGICAL SOCIETY.

Thursday, September 20th—Third Day.

Dr. R. W. Taylor read a paper on

LICHEN RUBER AS OBSERVED IN AMERICA, AND ITS DIFFERENTIATION FROM LICHEN PLANUS.

Prior to 1874 nothing was known in America of lichen ruber except the knowledge derived from Hebra's description. Lichen planus was well known in England, and we first learned to know the disease from the writings of Wilson and Fox. The Germans, at this time, knew nothing of lichen planus. At this time a series of typical cases of lichen planus were published in America. In this country lichen ruber is a very rare disease, and there are few opportunities for its study.

Dr. Taylor has had under observation two characteristic cases, in one of which the disease ran its course twice. A study of these cases should convince anyone that lichen ruber is a distinct morbid entity. Sixty-four personally recorded cases of lichen planus serve as basis for a table of differential diagnosis. The case reported was one of a female, aged thirty-seven, who came from Europe in 1884, and had her first attack at once. In March of the present year the patient came under the author's observation with an eruption which had begun as a group of pimples on the neck, and spread downward. At the date of writing, the disease has existed six months. He divides lichen ruber into three stages: 1. Stage of isolation of the papules; 2. Stage of coalescence of the papules; and, 3. The resulting chronic infiltrated, pigmented, and scaly stage.

When the papules are fully developed, numerous, and distinctly clustered in groups, they may perhaps be mistaken for a short time for lichen planus, particularly if they occur on the inner surfaces of the arms and near the wrists, on the abdomen, or on the antero-inner surface of the thighs or legs. Under no other circumstances can a trained observer confound the two diseases.

In inveterate cases, such as Hebra first observed, the whole integument may become transformed into a harsh, nutmeg-grater or file-like tissue. Particular attention is called to the condition of the nails, which are dull white or dirty yellow, rough, serrated, and four times their normal thickness. There is no concomitant nail affection in lichen planus. The paper shows that in America lichen ruber presents the same characteristics as in Germany, but it has not yet been seen here in the deadly form first described by Hebra. The disease has only one short stage in which it can, by any possibility, be mistaken by a trained clinician for lichen planus. Lichen ruber slowly but surely tends to extend; lichen planus remains indolent and localized. The first is attended by emaciation and possibly death, while the latter, as a rule, has no systemic reaction.

Dr. G. H. Fox read a paper having for title

THE NON-IDENTITY OF LICHEN PLANUS AND LICHEN RUBER,

in which he reported a number of cases to illustrate his position in maintaining that the two diseases are distinct and should not be confounded.

Dr. Sherwell said lichen was the most important subject brought before the Society, because of the still open questions and the attention the question is now receiving. There is a large consensus of ideas as to the non-identity of the two diseases. He believes absolutely in the non-identity. Clinically, almost all the facts go to prove this. He had seen a few typical cases of lichen ruber. In lichen planus the general health is not profoundly affected, while in the other the marasmus and ill-health lead to death.

Dr. Bronson thought the thorough manner in which the subject had now been presented would go far to settle the question, or at least aid in its study. He had long believed in the non-identity. Presuming that the diseases were alike in their pathological anatomy, the clinical features are so unlike that they must be looked upon as distinct.

Dr. Bulkley thought it a strong point that no one had ever seen the one disease developed or engrafted upon the other.

The old lichen simplex he believes in, but many cases of lichen ruber were probably in olden times included under it. He thought the paper of Dr. Robinson one of the finest he had ever heard upon a dermatological subject. He has reported two cases with lesions first appearing upon the glans penis. He believes thoroughly in the non-identity.

Dr. Atkinson agrees with those who have spoken. He has never treated lichen ruber.

Dr. Heitzmann said lichen is a term used in various ways. He thought Hebra had called these cases of lichen planus chronic eczema in the early days. Now he himself is convinced that the disease differs from lichen ruber. Eczema papulosum surely differs from lichen ruber planus.

In all cases of lichen planus he has used salicylic acid, with curative effect.

Dr. Robinson said, regarding pathological anatomy, that he had omitted this from his paper, making the difference not only upon this, but the clinical history and results of treatment.

He would not consider it proof of the identity if a single case of lichen ruber should develop lichen ruber. Arsenic has not much effect on lichen planus. He has been unable to cure with it, but has cured certain cases with iodide of potassium and colchicum in a week's time.

Dr. Taylor said he had microscopic demonstrations to substantiate his views. He did not believe the two diseases were interchangeable. The case of lichen ruber now under observation is typical. The nails have been lost twice in her previous attacks. He thinks she will recover from this, as from the other two attacks.

Dr. Bulkley then read a paper on

DERMATITIS PLANTARIS AND PALMARIS.

The term, he said, had not been hastily applied, but used to indicate a definite inflammatory condition. After reviewing the various dermatoses affecting the palms and soles, it was pointed out how the affection now described differs from them.

Notes of three cases are given; one in which there were several relapses. In the first case the palms had peeled repeatedly over a period of many years. It was preceded by malaise and indigestion for a week previous to the desquamation, such as is seen in scarlatina, leaving a red painful, denuded surface. The soles peeled as well in some attacks. The other cases were attended with burning or tingling sensations before the desquamation, and signs of impaired health were usually present. The temperature of the palm was found higher than that of the back of the hand. Borax lotion and astringent ointments were used with benefit. Duhring regards this condition as a localized dermatitis exfoliativa, but the author cannot accept this view. The data are too few for conclusions, but the cause must be looked for in the nervous system. The neurotic element was marked in two of the cases. There was no marked perspiration.

Dr. Heitzmann said we all meet with unusual cases. He had recently had a case in which the palms had exfoliated since childhood, but there was perspiration and augmentation of hairs upon the backs of the hands. He had named it dermatitis exfoliativa.

Dr. Hyde had a cast of the entire palm, which had exfoliated complete, just as Dr. Bulkley had one of the entire sole.

He had read a paper last year with the same title describing similar recurrent disorders.

The change in the hairs is very remarkable in some of the cases. He regards the condition as an external evidence of central trouble.

Dr. Morrow thought a central nerve-trouble was present. The term dermatitis exfoliativa was sometimes applied to pityriasis rubra, which he regarded as an unfortunate use of terms. As the exfoliation had extended to other parts in one of the reported cases, the designation did not cover the picture. He had seen such cases due to drugs.

Dr. Bronson said there is a peculiar form of inflammation attended with desquamation which he thought had been properly named in the paper.

Dr. Atkinson said he had seen cases due to the action of quinine, and asked if it had been excluded. Cases had been observed in which complete exfoliation could be produced at will by giving quinine. Effects of drug-ingestion should always be excluded.

Dr. Bulkley said there was a remarkable slowing of the pulse in one case, and white corpuscles were found in excess in the blood.

Quinine was excluded in one case, but one patient took it, as the patient was improving. He had seen cases of exfoliation due to quinine, but this is a distinct condition.

Other papers were read by Dr. A. Van Harlingen, of Philadelphia, on "Note of a Case of Filaria Medinensis," illustrated by a colored plate; one by Dr. R. W. Taylor, of New York, on "So-called Acne Anthracoide Iodopotassique;" and one by Dr. C. Heitzmann, of New York, on "Kraurosis of the Vulva (Breisky)."

The Association adjourned, to meet next year at Young's Hotel in Boston.

Dr. Graham, of Toronto, Canada, was elected President for the ensuing year.

AMERICAN ORTHOPEDIC ASSOCIATION.

Thursday, September 20th—Third Day.

Dr. Benj. Lee, of Philadelphia, read a paper on

HÆMATOMA ORIS AS A SIGN OF INJURY TO THE SPINE IN THE SUPERIOR CERVICAL REGION.

This condition consists in a gradual swelling of the organ, non-inflammatory in its nature, slightly painful and sensitive, or not at all so, which, as it progresses, destroys completely the natural shape of the ear, obliterating all the convolutions, until it looks as much as anything like a great purple egg-plum attached to the side of the head. After an indefinite period the tumefaction begins to diminish, the skin loses its tenseness, and shrivels, and the final result is a shrunken, seamed, and distorted member. Not infrequently the ear bursts and a considerable amount of blood is discharged. As to the cause of this curious pathological change, which is so well recognized that it has come to be called the "insane ear," authorities differ. (The authorities were then given.) The author's own conclusions are: First, that this curious pathological condition is idiopathic, never traumatic. Second, that the local tissue-change which makes the extravasation possible, is dependent upon a degenerative alteration in the nerve-centre which controls the circulatory apparatus of the auricle, involving or not the larger arterial branches.

The paper was discussed by Drs. L. H. Sayre, Vance, and Ketch.

Dr. A. J. Steele, of St. Louis, reported

TWO KNEE-JOINT EXCISIONS,

the first in a lad with chronic fungoid and suppurative joint disease, which had been going on from early childhood; the second in a young woman, with right-angled anchylosis of nine years' standing, resulting from injury, and doubtless subsequent acute synovitis. In the first case the joint was rapidly going on to destruction, and the constitution breaking down; in the second the inconvenience in walking prompted measures for relief. The results in both cases were good. Photographs were shown.

Drs. Whitehead, L. A. Sayre, Ridlon, and L. H. Sayre took part in the discussion of the paper.

Dr. R. W. Lovett, of Boston, then read a paper entitled

AN EXPERIMENTAL STUDY OF FIXATION AND TRACTION IN HIP-DISEASE.

American traction-splints are criticised by English surgeons on the ground that they afford imperfect fixation. With a view to ascertaining how much fixation traction alone affords, some experiments were made upon a healthy child. It was found that with four pounds traction, exerted by means of a hip-splint with one perineal band, in walking 35° of motion took place. With the highest endurable traction (eight pounds) 15° of motion took place. Evidently, then, traction alone cannot afford fixation to a diseased joint. It does not seem likely, either, that it separates the joint surfaces, inasmuch as in the case experimented upon the power of the thigh muscles was roughly estimated to be thirty-six pounds. With all their force when set in muscular spasm, they would pull the head of the bone against the acetabulum with more than that power, and the antagonizing force is only eight pounds at most. Experiments as to distraction upon the cadaver do not reproduce the clinical conditions, inasmuch as muscular spasm, the most important factor of all, is left out of account.

A hip-splint providing fixation as well as traction was shown, being merely a slightly modified combination of the English Thomas splint with the American traction-splint. Its best use is in bad cases where any joint motion does harm, and in cases where deformity is present, inasmuch as it is possible to correct the deformity while the child goes about on crutches. The paper was discussed by Drs. L. A. Sayre, Ridlon (who showed a body-piece attached to a long-traction hip for the sake of giving better fixation, and an easy means of giving abduction or adduction), Bradford, Park, Steele, Moore, and Shaffer.

Dr. R. W. Whitehead, of Denver, then read a paper on

THE OPERATIVE AND MECHANICAL TREATMENT OF SOME JOINT DISEASES AND INJURIES,

with especial reference to the hip-, knee-, and elbow-joints, with illustrative cases.

The putting of a crooked leg into a straight splint was deprecated in the strongest terms. In hip-disease with deformity, in certain cases tenotomy was used with *brisement forcé*, and the subsequent application of a traction splint. The result was good, with motion. Another case was reported where there was anchylosis at the hip-joint. The treatment was the same as above mentioned. Other cases were reported where tenotomy and *brisement forcé* were not used, and good results were obtained by weight and pulley, or with the long-traction splint.

Cases of partial resection of the knee-joint were then related. It was pointed out that when subluxation of the tibia backward occurs, the condyles of the femur become abnormally elongated by growth, so that reposition is impossible without at least a partial resection. It was believed that so far as possible the ligaments should be respected, and that the patella should not in very many cases be removed. A felt splint with an arrangement for giving traction and counter-traction, as also an apparatus for the elbow-joint was described. Many photographs were shown. The paper was discussed by Drs. Lee, Moore, Ridlon, Shaffer, and Phelps.

Dr. V. P. Gibney, of New York, read a paper on

IMMOBILIZATION IN ARTICULAR DISEASE.

The question which the author put was, Whether fixation of a joint, about which disease of the bones exists, is detrimental, or contributes in the least to permanent impairment of the functions of the joint? The author believed the function of an organ in health is modified in proportion to the impairment of that organ. The consensus of opinion, as expressed by the leading surgeons of New York City, within the past two or three years, is to the effect that the best possible results in elbow-joint injuries are obtained by perfect immobilization after the part has been placed in normal position. In the use of plaster-of-Paris dressings for the knee the author's experience is that the better the fit secured by the plaster dressing, and the longer kept uninterruptedly applied, the greater was the disappointment at not finding the expected anchylosis; in other words, the range of motion was increased by the prolonged fixation. Whatever anchylosis occurs in a joint which has been subjected to immobilization occurs by reason not of immobilization but of the nature and intensity of the inflammation, and of the inefficiency of the apparatus employed.

Dr. R. W. Lovett then exhibited the following appliances, from the Children's Hospital, Out-Patient Department, of Boston:

A series of modifications of Taylor's back-brace for cervical Pott's disease; perineal bands; extension head-piece for plaster-jacket; flat-foot plate; outside Taylor shoe; Bradford frame; Thomas' knee-splint with screws for adjustable length, and apparatus for measuring for it; apparatus for double infantile paralysis.

Dr. Ridlon, of New York, exhibited a box for shoe in using Thomas' caliper-splint; and Thomas' knee-splint, modified for infantile paralysis.

Dr. Samuel Ketch, of New York, read a paper entitled

REMARKS ON LATERAL CURVATURE AND ITS EARLY TREATMENT.

He brought out especially the relationship of habit, puberty, and other supposed etiological factors to this deformity. The former was considered as being rather a result than a cause of the deformity, the author stating that he had never seen a case of rotary lateral curvature resulting solely from habit. Puberty he considered as being in itself no direct cause, it being simply a period of life at which the deformity already existing progresses more rapidly and is brought into greater prominence by coincident events, such as greater alteration of form, dress, etc. In the matter of treatment he considered early diagnosis of the greatest importance, and that this disease principally is one of early life the author thought proven by his investigations reported in an article entitled "Remarks on Lateral Curvature, with Special Reference to its Occurrence in Children," published in The Medical Record, April 24, 1886. It is then at this time, between birth and seven years, that we should look for and begin to treat these cases in order to bring them to a successful issue. The author, as a rule, deprecated the use of an apparatus in very young children, relying principally on exercises, gymnastics, posture, and recumbency.

The paper was discussed by Drs. L. A. Sayre, Lee, and Whitehead.

The following papers were read by title: "An Effectual and Inexpensive Method for the Mechanical Treatment of Pott's Disease," by Dr. C. F. Stillman, of New York; "Acute Epiphysitis in Infants," by Dr. Dillon Brown, of New York; "Description of an Apparatus for Measuring any Inequality in the Length of the Lower Extremities," by Dr. T. G. Morton, of Philadelphia; "The Surgical and Mechanical Treatment of the Deformities of Spinal and Cerebral Paralysis," by Dr. A. Sydney Roberts, of Philadelphia; "Double Hip-Disease, a Report of Fourteen Consecutive Cases, with some Conclusions," by Dr. John Ridlon, of New York; "Distraction of the Head of the Femur as a Result of Continuous Extension," by Dr. E. G. Brockett, of Boston.

The following officers were elected for the ensuing year: *President*, Dr. E. H. Bradford, of Boston; *First Vice-President*, Dr. Benjamin Lee, of Philadelphia; *Second Vice-President*, Dr. V. P. Gibney, of New York; *Secretary and Treasurer*, Dr. R. W. Lovett, of Boston.

The Association then adjourned.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Thursday, September 20th—Third Day.

Dr. Charles H. Knight, of New York, read a paper on

CONGENITAL BONY OCCLUSION OF THE POSTERIOR NARES.

Total occlusion is extremely rare, especially when caused by congenital bony tumor. Reference was made to reported cases, and especially that reported by Dr. Jarvis, of New York. The whole literature of the subject had been thoroughly worked up. Treated by perforating with nasal trephine, run by electro-motor, and subsequent use of galvano-cautery, it showed great persistence in closing after each operation, but soft tissue instead of bony. Sense of smell greatly improved, even when temporarily closed. There still remains a tendency to dryness of mucous membrane on that side of the nose. In operating and diagnosing was aided by examining with the finger behind the palate.

Dr. Allen reported a case of bilateral occlusion where he operated with large drill.

Dr. C. C. Rice, of New York, presented a communication entitled

ANTISEPTIC NASAL SURGERY.

His experience is that there are present in the nose, heat, moisture, foreign matter, extract from air containing numberless germs, and, in fact, every condition to favor decomposition and the infection of any cut surface. Tissues, in swelling after operating, block up the nose, interfering with drainage and enclosing small fragments of soft or bony tissue that are almost certain to decompose; tissue also partly severed and still hanging to wound; excessive bleeding also tempts one to pack the nostril, which, along with use of persulphate of iron is almost certain to show symptoms in from eight to twenty-four hours. Hard to use antiseptic dressing as wet by constant discharge.

He mentioned a large number of cases where blood poisoning had resulted to a dangerous degree, some of which had been reported. Has frequently seen temperature rapidly run up to 103° to 104°F., with intense nervousness, headache, etc. Remove tampons, if used, and douche thoroughly from both anterior and posterior nares with solution of hydrogen dioxide, boracic acid, salicylic acid, or bichloride of mercury. Fifty per cent. of cases operated on have same temperature. Erysipelas is comparatively common after operations in nasal cavities. Advocates the thoroughly douching out of nostrils with a quart or more of antiseptic solution, and take as much care with the sterilizing of instruments and hands as is usual with surgeons. Above all, thorough cleanliness. Never tampon nose even with antiseptic packing. Prefers liquid medication to powders. Never take away more tissue than necessary.

A lengthy discussion indorsed the vital importance of antiseptic nasal surgery.

Dr. Charles E. Sajous, of Philadelphia, read a paper on

THE TREATMENT OF SOME FORMS OF HOARSENESS.

The plan of treatment was to remove thickening and vascularity of cords, not by severe surgical interference, but by means of chromic acid fused upon aluminium applicator. A very small area was treated from time to time, till the whole surface had been freed from the dilated vessels. Successful cases were reported.

Dr. J. C. Mulhall, of St. Louis, read a paper, entitled

THE CURE OF FALSETTO VOICE.

The case reported was cured, not by medication, but by mental impression and patiently teaching the patient the proper use of the laryngeal muscles, to produce a lower register for speaking. He was greatly aided by putting the head in such a position as to interfere with the production of higher notes.

Dr. A. W. MacCoy, of Philadelphia, reported

A CASE OF SARCOMA OF THE TONSIL.

Mulatto girl, aged forty-five. First appearance as simple case of follicular tonsillitis. Three weeks later large fissure appeared at the centre with adherent slough. Several weeks later began to change color at centre (grayish white), with loss of tissue and œdematous margin. Soon red growth appeared behind soft palate, spreading to Eustachian tube and posterior pillar of the pharynx, with thin processes extending over posterior wall of pharynx. The next extension was to infiltrate the palate and uvula, causing sloughing. Between the sixth and seventh month swallowing was difficult from infiltration at base of tongue. At eighth month growth more rapid, involving gums and cheek, so that mouth could not be closed. Submaxillary gland and lymphatics involved. Deglutition almost impossible, and interference with breathing threatens resort to tracheotomy. At tenth month great loss of weight and rapidly failing. Died in carriage while being moved by a relative contrary to advice. No autopsy was obtained. Donovan's solution was used, increasing dose to fourteen drops three times a day without gastric disturbance.

In one thousand cases of throat tumors recorded during a number of years in four London hospitals, and reported by Dr. W. R. Williams, only nine primary tumors of tonsil, and but one sarcomatous.

Dr. S. W. Langmaid, of Boston, exhibited

A SPECIMEN OF LARYNGEAL PAPILLOMA FROM A CHILD.

The papillomatous mass was large and attached to both cords. The larynx was for the most part filled by the growth.

Dr. Franklin H. Hooper, of Boston, presented a communication entitled

THE EFFECTS OF VARYING RATES OF STIMULATION ON THE ACTION OF THE RECURRENT LARYNGEAL NERVE.

Experiments were tried on dogs and cats by galvanizing both recurrent laryngeal nerves, and varying both the intensity of the current and the number of vibrations.

When the vibrations were between twenty and thirty per minute, the vocal cords were separated unless strong current. When between twenty-eight and forty they were closed in front and separated posteriorly.

An intense current closed them even when there were but twenty vibrations. Cuts required double the number of vibrations to cause closure.

Dr. F. H. Bosworth, of New York, presented

A REPORT OF CASES OF PHARYNGEAL AND LARYNGEAL PARALYSIS DUE TO BULBAR LESIONS.

Three causes of laryngeal paralysis: Injury or irritation to terminal filaments; injury to, or pressure on trunk of recurrent laryngeal; irritation of central origin in medulla. Improbable that it can be due to any but last cause when the paralysis is bilateral. Difficult to find any case where pressure on both recurrent laryngeal nerves. Cases mentioned where the bilateral paralysis was forerunner of locomotor ataxia, or soon had other forms of paralysis make their appearance. Forty or fifty cases he had on record, which were verified by post-mortem examination, and the cause found to be bulbar lesion or clot. He has found no evidence of there being a laryngeal centre in the cortex.

Dr. E. Fletcher Ingals, of Chicago, read a paper on

SUBGLOTTIC LARYNGEAL ENCHONDROMA.

This affection has only twice been treated successfully by endo laryngeal operations. Dr. Ingals gave in detail the history of a case which had been greatly benefited by the occasional application of strong chromic acid. On account of business engagements the patient had been very irregular in attendance. In all, but six applications had been made, and at irregular intervals of from one to five months, and had caused a reduction in the size of the tumor from 7 mm. in height, and 12 mm. in diameter, to one tenth that size. The author felt confident that it could be completely eradicated by a few more applications. The chromic acid was fused upon an aluminium applicator, and a small section of rubber tube slipped over it, and so cut as to leave only the end and a small place at the side. Thus surrounding tissues were protected.

Dr. W. H. Daly, of Pittsburg, followed with a communication entitled

MILD MEASURES IN THE TREATMENT OF INTRA-NASAL HYPERTROPHIES.

Accident caused the adoption of the following line of treatment: A case had become frightened and refused further treatment, as the first cut was being made in removing, with serrated scissors, a large anterior turbinated hypertrophy. The incisions had bled freely at the time. The patient made a hurried escape and was not seen for a year, when it was found that the hypertrophy on that side had contracted to normal size. Now treats similar cases by making small punctures from time to time so as to allow bleeding to extent of one to three ounces. The results have been most excellent, especially where the tissue was very vascular and soft rather than true hypertrophy. The author fears galvano-cautery on account of occasional disagreeable results, while milder measures prove more satisfactory.

THE AMERICAN CLIMATOLOGICAL SOCIETY.

Thursday, September 20th—Third Day.

Dr. J. T. Whittaker, of Cincinnati, read a paper on

CONDITIONS WHICH TEND TO RENDER THE ATMOSPHERE OF A LOCALITY ASEPTIC.

He reviewed the opinions of authors as to the agency which the air has in carrying the germs of disease. The air of different localities varies a great deal in the number of micro-organisms, the air of cities containing more than that of the country. The air at sea, at the distance of a little over a hundred miles, is absolutely free from micro-organisms except in the presence of a land-breeze. The large number of micro-organisms found in dwelling-houses would lead us to infer that infectious diseases are usually, if not always, contracted in dwelling-houses. The conditions necessary to make the air in a house aseptic were considered. He recommended furnaces which should take their air from the top of the house.

Dr. Johnson, of Chicago, remarked that one of the difficulties of producing an aseptic atmosphere is, that what will destroy one micro-organism will not destroy another. He spoke of the danger of large numbers of micro-organisms found in health-resorts.

Dr. Taylor, of San Antonio, spoke of the prevalence of septic diseases in localities where people are shut up in their houses for a great part of the year.

Dr. Daly, of Pittsburg, doubts if it is best to take the air for furnaces from the tops of houses. He considered the house described by Dr. Whittaker was an ideal house which could never be built, but he recommended the careful examination of houses as they exist.

Dr. Wilson, of Philadelphia, said that dilution was the true means of rendering the air of our houses aseptic. There is more apathy than there should be about the ravages of pulmonary consumption, which are more formidable than even the epidemics of the middle ages, and we should take proper precautions against the spread of consumption.

Dr. A. H. Smith, of New York, remarked that he believed the time would come when the physician who neglected to take proper precautions to prevent the infection of healthy persons by consumptives would be considered as guilty as one who exposed his patient to the small-pox without vaccination.

Dr. Frank Bosworth, of New York, made remarks on

THE RELATION OF THE NASAL AND NEUROTIC FACTORS IN THE ETIOLOGY OF ASTHMA.

He does not believe in the spasmodic origin of asthmatic attacks. He believes that the disease is a neurosis, according to the theory of Weber. The serous exudation of the nasal and bronchial mucous membranes are reciprocal, the exudation of one adapting itself to the exudation of the other; anæmia of the one also being associated with anæmia of the other. On account of the sympathy between the two membranes, certain conditions of the nasal membrane may cause attacks of asthma.

Dr. E. L. Shurly, of Detroit, spoke of a series of experiments on dogs to produce asthmatic paroxysms, and these led him to discard the spasmodic theory of asthma. He does not believe in the nasal origin of asthma. The majority of nasal passages of asthmatics that he has examined in the past four years he thinks have been healthy.

Dr. Daly, of Pittsburg, emphasized the difference in experimental researches on animals and the conditions of disease in human beings. He believes there are a certain number of cases of hay asthma which can be cured by placing the naso-pharynx in a healthy condition, but this is not so in all cases.

Dr. A. H. Smith, of New York, thinks the causation of asthma is a many-sided question. Not only the swelling of the mucous membrane, but interference with the circulation of the blood through the lungs, may have something to do with the asthmatic attack. The frequent good results of operations on the nose in such cases has much impressed him of late years.

Dr. Beverley Robinson, of New York, thinks that nasal disease may have a causative relation to asthma. He remarked, however, that he had seen many cases of nasal obstruction in those who had never had asthma.

Dr. Bosworth said that, of 80 of his cases of asthma, 42 had been cured and 30 much benefited by nasal treatment alone. In 5 of these cases the result was unknown, and only 3 were not benefited. He thinks this a strong argument in favor of the nasal cause of asthma.

Dr. J. L. Wilson, of Philadelphia, read a paper on

CLIMATE AND BRIGHT'S DISEASE.

Renal disease prevails most where the heat for the greater part of the year might be called temperate. Change of climate in chronic Bright's disease is of great value, and is, perhaps, as important as in consumption. Little notice is taken in text-books of the change of climate. The dangers of abrupt changes of climate or of long journeys by rail must not be overlooked.

Dr. Taylor, of San Antonio, emphasized the value of change of climate in Bright's disease in going from the Northern to the Southern part of the United States.

Dr. Solly, of Colorado Springs, said sending cases of Bright's disease to high altitudes was usually dangerous, but he had seen cases do well in Colorado. He believes the chief point to be thought of is the action of the skin and the effect the climate will have upon that.

Dr. Loomis remarked that his advising change, or not, in these cases has depended upon the condition of the heart; when we have signs of heart failure we are risking the lives of our patients by sending them away.

Dr. M. K. Taylor, U.S.A., read a paper on

CLIMATIC CHARACTERISTICS OF TEXAS.

It is impossible, within the limits allowed, to do justice to so large an area of country as Texas. The rainfalls and the elevation of different parts of the State were dwelt upon. He mentioned the dryness of the air in some sections, which equals that of the Nile region. The average number of days in which the thermometer goes below zero at San Antonio is fourteen in the year, and there is rarely any dew.

Dr. J. J. Levich, of Philadelphia, read a paper on

WEAK HEARTS AS AFFECTED BY CLIMATE AND TEMPERATURE.

He believes the strain brought upon the heart by severe exercise may produce effects which last often for a long time, and this condition he calls, for want of a better name, weak heart. After considering the symptoms he insists upon the importance of recognizing the condition early. The most important part of the treatment is to avoid the cause, and change of climate. He recommends small doses of nux vomica. Although digitalis in proper cases is valuable, he says a word of caution against its improper use; it is not well to give it in these cases.

Dr. A. L. Loomis remarked that there were cases of heart failure for which there is apparently no cause, but he believes that in most of these cases there is dilatation, most frequently of the right side, and this dilatation is not necessarily permanent.

Dr. J. M. Anders, of Philadelphia, read a paper on

TEMPERATURE AND RELATIVE HUMIDITY, AND THEIR RELATIONS TO HEALTH AND DISEASE.

He drew a number of conclusions upon the subject of his paper.

Dr. I. H. Platt, of Lakewood, N. J., read a paper on

SUGGESTIONS REGARDING THE MANAGEMENT OF PHTHISICAL PATIENTS UNDERGOING CLIMATIC TREATMENT.

The benefits of climatic treatment depend, first, upon choosing the proper climate, and, second, upon the proper regulation of the life. He considered what we should seek for in change of climate and the mode of life to be adopted by the patients wherever they may be sent. He deprecates the association of a large number of patients together. He considered the construction of the houses in which patients should live.

Dr. W. Matthews, U.S.A., read a paper entitled

FURTHER CONTRIBUTIONS TO THE STUDY OF CONSUMPTION AMONG THE INDIANS.

The rate of consumption, especially scrofulous, among Indians is high and is increasing, which may be accounted for by the change of life among those who have given up their wild life and are living on reservations. Scrofula is common among these people.

Dr. D. M. Cammann, of New York, read a paper on

OBSERVATIONS ON THE USE OF TEREBENE.

He found terebene useful in bronchial affections. It lessened the expectoration and rendered it more watery. It seldom disordered the stomach. It was found to be more useful in cases of emphysema and bronchitis than in cases of phthisis. It is diurectic as well as expectorant, relieves flatulence, and seems to have a resolvent action on pleuritic adhesions.

The Association then adjourned.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 9 to September 15, 1888.

Page, Charles, Colonel and Assistant Surgeon-General, Medical Director of the Department. Will proceed to Forts Riley and Hays, Kan., near Denver, and Forts Crawford, Lewis, and Lyon, Col., and return on public business. The travel enjoined is necessary for the public service. Headquarters Department of the Missouri, Fort Leavenworth, Kan., September 7, 1888. S. O 114.

Norris, Basil, Lieutenant-Colonel and Medical Director. To proceed to Fort Klamath, inspect the Medical Department at that post, and upon completion thereof return to Headquarters, Department of the Columbia, Vancouver Barracks, W. Ter. S. O. 103, September 3, 1888.

Caldwell, Daniel G., Major and Surgeon, is granted two months leave of absence, from September 14, 1888. A. G. O., S. O. 210, September 10, 1888.

Ainsworth, Fred. C., Captain and Assistant Surgeon, will, by direction of the Secretary of War, proceed to Kennebec Arsenal, Augusta, Me., on public business connected with the Medical Department of the Army; on completion thereof will return to his station in this city. A. G. O., S. O. 211, September 11, 1888, Washington, D. C.

Banister, John M., Captain and Assistant Surgeon, is granted two months leave of absence, with permission to apply for an extension of one month, to take effect when his services can be spared. A. G. O., S. O. 211, September 10, 1888.

Strong, Norton, Captain and Assistant Surgeon. By direction of the Acting Secretary of War will report in person, at 11 o'clock A.M., October 18, 1888, to Brigadier-General John R. Brooke, President of the Retiring Board, in session at Omaha, Neb., to give testimony in a case pending before the Board. Upon completion of this duty he will return to his proper station. By paragraph 9, S. O. 212, A. G. O., September 12, 1888.

Jarvis, Nathan S., First Lieutenant and Assistant Surgeon, is granted one month's extension of leave of absence, on Surgeon's certificate of disability. A. G. O., S. O. 210, September 10, 1888.

Official List of Changes in the Medical Corps of the United States Navy for the week ending September 15, 1888.

Lung, George A., Assistant Surgeon. Ordered to Receiving Ship Vermont, Navy Yard, New York.

A Druggist in Lewiston, Me, is said to have received the following order: "Mister Druggist: Please send ipe cac enough to throw up a four-year-old girl."

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, September 22, 1888.

THE CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

THE first triennial meeting of this Congress, which was held in Washington during the present week, has been an unqualified success, as regards both the number and professional standing of those who took part in it, and the scientific character of the papers read and discussed at the meetings of the component societies.

Although the different societies held business and scientific meetings on the morning of Tuesday, the Congress itself did not spring into existence until later.

At one o'clock on the afternoon of that day a meeting was held in the main hall of the Grand Army building. It was called to order by Dr. Pepper, Chairman of the Committee of Arrangements, who declared the Congress formally opened, and introduced the President, Dr. John S. Billings. After a few words by the President, an address of welcome was made by Dr. Busey, Chairman of the Committee of Arrangements. Then the by-laws were read and adopted, and the members dispersed to attend the meetings of their respective societies.

The Congress at its birth was composed of eleven societies, and has admitted at this session the American Gynecological Society. Two new national societies, the American Pediatric Association and the Association of American Anatomists, were organized during the session, and have made application for admission to the Congress. The American Association of Obstetricians and Gynecologists has also made application for admission.

The social feature of this Congress was less prominent than it usually is on such occasions, but this could not be otherwise, for the general meetings were held in the evening, thus occupying the time with scientific work. Nevertheless, ample opportunity was given for enjoyment. On Monday evening a dinner was tendered to the guests of the Congress. On Tuesday evening there was an informal reception held at the close of the general meeting. On Wednesday afternoon a reception was given to the members by the President and Mrs. Cleveland, and on Thursday evening, after the address of Dr. Billings, the associates and guests, with their ladies, met in a social reunion in the building of the Army Medical Museum and Library.

The number of registered associates of the Congress was nearly four hundred, and there were many more who were in attendance at the meetings, but were not members of any of the component societies. The foreign guests were conspicuous for their numbers as well as their high scientific reputation.

The organizers of the Congress have every reason to be proud of their work, and the wisdom of their action has been amply justified by the brilliant success of this meeting.

News of the Week.

THE NEW YORK POLYCLINIC.—Dr. Charles Stedman Bull has been elected Professor of Ophthalmology, and Dr. Henry N. Heineman, Professor of General Medicine. No other changes have occurred in the Faculty.

THE AUTOPSY ON PROFESSOR PROCTOR produced negative results, as Drs. Prudden and Biggs testify that advanced decomposition prevented the recognition of the usual pathological lesions of yellow fever. They are of the opinion, however, that the clinical history was that of yellow fever.

THE YELLOW FEVER in Jacksonville, Fla., continues on the increase, and is reported to be of a very malignant type. The recent unfavorable weather tells very seriously upon the mortality. The total number of cases to date is 1,464, with 185 deaths. The disease is spreading in Hendersonville, S. C., and has appeared in Decatur and Mobile, Ala., in Jackson, Miss., and Atlanta, Ga.

THE HOMŒOPATHIC CHARITY HOSPITAL TROUBLE.—The President of the Medical Board of this hospital, Dr. E. Guernsey, desires us to state that there is no difficulty in obtaining internes, notwithstanding the high order of entrance qualification demanded, and that the institution is in a prosperous condition.

SALICIN AND BROMIDE OF POTASSIUM IN TETANUS.—Dr. Butlin reports, in the *British Medical Journal*, a case of traumatic tetanus, occurring in a man, aged twenty-six, cured by large doses of salicin and potassium bromide. The drugs were given in doses of twenty grains each, every two or four hours.

IODIDE OF POTASSIUM IN PSORIASIS. — Dr. Haslung reports fifty cases of psoriasis treated by large doses of potassium iodide. Of these cases forty were cured, four were considerably benefited, and in six no improvement was noted. The duration of the treatment varied from seventeen days to eleven weeks.

CAMPHORIC ACID is recommended by Max Reichert in the treatment of various affections of the skin and mucous membranes. He has obtained very satisfactory results from its use in tonsillitis and laryngitis, and in eczema of the hands and acne. He employs solutions of one-fourth to six per cent. in alcohol and water, the weaker solutions being for acute cases, the stronger for chronic affections.

AMAUROSIS FROM A CARIOUS TOOTH.—Dr. Riva reports the case of a woman, aged thirty, who was wholly blind in one eye. She suffered from a carious tooth on this side, and after its extraction the vision was restored. —*Revista de Ciencias Médicas.*

A REVIEW OF SOME POINTS IN GYNÆCOLOGY.[1]

By S. C. GORDON, M.D.,

PORTLAND, ME.

THOMAS said several years since that the treatment of diseases of women was largely surgical. Since then there have been very rapid strides in the same direction. In fact, the same may be said of almost any one of the various branches of the entire domain of medical science. They have all become more or less surgical.

Dr. E. M. Moore, in his "Address in Surgery" before the American Medical Association in May, 1888, used the following language: "At present it seems as if the future of the profession must be largely surgical. With a single bound the limitations set by the physician have been put aside. The surgeon opens the various cavities of the body, not only to repair injury, but to remove the results of morbid processes. If the physician fails to rectify the abnormal chemistry of the spleen, the surgeon removes it; if nephritis or pyelitis with organic disease of one kidney, bearing the patient down, the surgeon takes it away. If disease of the bowel obstructs, he cuts it out and joins the healthy ends of the cut. If the lungs are the seat of abscess, he punctures and drains them. If the brain has an abscess pressing on and endangering life, he punctures, drains, and renders the wound aseptic. It is difficult at this moment to define the possibilities of modern surgery. It is a fit representative of the time we live in; the combination of science and action."

But when we come back to the branch of medicine known as gynæcology, what do we find, in the treatment of diseases peculiar to women, that could not be classed strictly as surgical, aside from the general medication required by patients exhausted by long-continued suffering? And here the specialist should have, and must have, to be successful, a skill in general treatment which can be obtained only by a clinical experience in general practice.

The routine of frequent "applications" and so-called "local treatment," by the various remedies used, is deservedly falling into disfavor, and physicians are finding out, what many of their patients found out long ago, that they are doing but little good, and in many cases very much harm. In cases of pelvic exudate and chronic passive congestion, the results of inflammation, displacements, etc., much can be done by judicious men, by painting the vagina thoroughly with tincture of iodine, or, what I like much better, iodized phenol, and the local depletion by leeches, or scarifying glycerine packs, and the hot douches used for a reasonable time.

But all these modes of treatment are surgical. Intra-uterine applications, as they are ordinarily made, have, in my opinion, done incalculable harm.

Under the most favorable circumstances, pelvic inflammation is extremely liable to follow their use. To do this in one's office and then allow the patient to walk or drive home is, I believe, highly dangerous. A very large proportion of the cases of pelvic abscess I have ever seen have been due to intra-uterine applications of some stimulating remedies, manipulations by sounds, dilatation by tents or some other form of dilator without the use of anæsthetics.

I am very nearly a convert to the views of Emmet, who practically believes that no application should be made to the uterine canal with an intention to cure disease existing there. In the first place, I find but few cases where disease exists there, and when found it is either an attack of inflammation, which does not tolerate local applications, or the result of such an attack, which is easily and rapidly removed by leeching, scarifying, and stimulating or vesicating remedies applied around the uterus.

If any disease in the cavity is found, such as thickening from passive congestion, with granular degeneration, I always make the treatment a surgical operation by etherizing the patient, dilating slowly but thoroughly for ten or fifteen minutes, curetting, and applying either pure carbolic acid or the iodized phenol. Any attempt to remove fungous growths from the uterine cavity should be done thoroughly or not at all. And to do this thoroughly one should always have his patient anæsthetized. I am well convinced that the shock consequent upon doing these things without ether is often the cause of inflammation, which would not ensue if the patient did not suffer. I fear the profession are not fully aware of the importance of the foregoing propositions, while I am satisfied that they are gradually becoming convinced that the former indiscriminate use of caustics and stimulating applications to the uterine cavity, together with the needless use of the sound, has been productive of much more harm than good, and are fast giving them up, with a consequent decrease of pelvic inflammation and abscess.

In this connection I would strongly urge the importance of an early opening and draining in all cases of pelvic abscess. I am sure this should be the practice in cases of abscess wherever found. The former teaching, that in certain localities abscess should be allowed to take its own course, has been all wrong, resulting in long chronic invalidism and death. In cases of long standing where the abscess-wall has become thick, I have found nothing so beneficial in removing the exudate as the iodized phenol and hot douche—always, of course, draining when practicable.

The phenol acts especially well in all those cases where are found posterior displacements of the uterus and appendages, with strong adhesions which prevent replacement and cause so much local suffering and reflex symptoms. These are among the most difficult cases that the gynæcologist encounters, and the exercise of the soundest common sense and of the most extreme care is required in properly treating them.

Haste and violent efforts at replacement may cause inflammation that will almost surely result in abscess or firmer adhesions. In a very few of these cases I have succeeded, by Schulter's method, in forcibly rupturing some of the adhesions, adjusting the pessary, and accomplishing a cure.

In a majority of cases, however, persevering in the use of the phenol, packs both moist and dry, pessaries worn for a few days at a time, very large and very hot douches, with care as to the general health, we can do much in way of relief and even cure. Care must be exercised in the use of hot douches, otherwise a state of chronic congestion will ensue; I am sure they have been much abused by being kept up too long. With all our efforts, seconded by the patient, under the most favorable circumstances, we shall find a large percentage of these cases, due to pelvic inflammation and other causes which produce organic changes in the uterine appendages, and in time induce reflex or hysterical symptoms, that get no relief from suffering even. And here is where the operation for removal of the appendages must be resorted to. The most faithful and persistent treatment, however long pursued, neither changes the local condition nor gives relief to the nervous or general neuralgic symptoms. The patient leads a miserable life of pain and nervous exhaustion, which frequently terminates in insanity—which at least grants the patient an oblivion to physical suffering.

---

[1] Read before the Maine Medical Association, June 13, 1888.

I have now operated forty times for removal of the uterine appendages for the relief of this class of invalids, and I can say with the utmost sincerity that I should not, in a single case, hesitate to advise the same thing under similar circumstances.

A very large majority of the patients are to-day thoroughly cured, and they bless the day they submitted to the operation.

Five have died, three or four are as yet unimproved, and perhaps may never be any better. They are certainly no worse, either physically or mentally, but even in some of these I do not despair, as the element of time has not yet had its full effect.

It is time that the profession should cease to condemn an operation which has done so much as this has for a class of women who have been an opprobrium to medical science, at least in the eyes of the public.

These sufferers have wandered from one physician to another, into and out of hospitals, from which they have been dismissed with the hope that they will be better when menstrual life ceases, or with a hint that they are better, if they could only think so. To my mind this is simply an apology for professional ignorance—as if any woman or man enjoys being miserable. Shame upon such teaching! It is unworthy a humane and intelligent profession like ours. We know better, and let us have the courage of our convictions, instead of making apologies for what we know to be right, in deference to some self-asserting wiseacres and an unintelligent public, who, on the slightest pretence, forsake the regular profession and run eagerly after the last fad, be it homœopathy, spiritualism, Christian science (which has neither Christianity nor science to commend it), or any other form of mind-cure.

I believe the profession generally, and in our own State particularly, are fast coming to a full sense of the importance of some more radical measures for treating this unfortunate class of cases. Reflex symptoms have a diseased centre, if we can only find it, and it is not scientific or humane to say that a patient who has lingered in this way is simply hysterical, and could act better if she tried. Much better find the centre and remove the disease, or remove the organ if it cannot be cured. Always try the former first.

Cancer of the uterus has long been another *bête noire* of the profession, while the public have been asking, "Is there no remedy for this terrible disease?"

The sentiment has now become crystallized in the profession that cancer is in the beginning a local disease, and the result of this belief is early removal of all growths of a suspicious character. Believing that cancer of the uterus is no exception to this rule, the advanced men are now making vaginal hysterectomy with far better results, both as regards operation and cure, than we have ever had by any other means.

From February 10th to April 15th, last, I made the operation three times, with two recoveries and one death.

Time alone can tell how valuable it will prove in these two cases, but so far they have done well—no signs of return.[1] I feel much safer than if I had made any other attempt at either relief or cure. So far as I know, these are the only cases of vaginal hysterectomy for cancer in this State. I am hopeful for the future of this comparatively new surgical operation.

In September last, I made a laparotomy for extra-uterine pregnancy (tubal). The diagnosis was made several days before by Dr. Hitchcock, of Rockland. I operated fifteen hours after rupture, and although peritonitis had developed it at once ceased, and the patient made a rapid and perfect recovery. I am sure, had I seen the case before rupture and been sure of the diagnosis, I should have advised operation at once. I can see no reason for delay, and the mortality attending the cases heretofore reported certainly justifies us in saying that the chances for life are much greater from laparotomy, immediately that a diagnosis is clearly made, than by fœticide by electricity or waiting for rupture.

This being the second recorded successful case in this country, we await further statistics before we can demonstrate it.

One other operation of the kind in this State was done by Dr. S. H. Weeks, within the past few months, but too late to save the patient.

I believe that the importance of making an early diagnosis, in cases of obscure symptoms of pregnancy, will awaken the profession to a more careful consideration of them, so that we shall soon adopt the idea that primary laparotomy will be the rule.

Even should electricity prove to do all that is claimed for it, there will be in many cases a foreign body in the abdominal cavity, where it is at all times liable to undergo decomposition, thus endangering the life of the patient constantly. Admitting that electricity is sure to kill the fœtus, it has been shown that it does not surely stop the growth of the placenta, so that under the most favorable conditions we have a foreign body which almost every wise and prudent man would feel unsafe about so long as it remains, and, were it anything else but a product of conception, would unhesitatingly advise removal. It seems then only a question of diagnosis that should cause any hesitation as to the best method of treatment.

My experience with saline cathartics early after abdominal section, especially if any signs of peritonitis appear, leads me to indorse the plan most cordially. In any event, I am satisfied that the former practice of keeping the bowels locked up for a week is detrimental to rapid recovery. Within the past year I have used a hot boracic solution, or, in absence of this, hot water to wash out the abdominal cavity after all sections. In many of the cases, especially where the patient was exhausted either before or during the operation, it has, in addition to its cleanly property, acted as a good stimulant.

Two years ago I reported to this Association my use of catgut for nearly all operations upon the uterus, vagina, and perineum. I had then not dared to try it alone for complete laceration of the perineum. Within the last year, however, I have made the operation for a bad case of complete laceration with catgut alone, and am very much pleased with the result. The patient suffered no pain, required no opiate, and the parts healed admirably, without even a drop of pus. I have no occasion now for silver wire for any kind of suture whatever.

For several years I have operated upon cases of lacerated cervix without submitting the patient to any prolonged preparatory treatment, so strongly insisted upon by Dr. Emmet.

Believing the condition ordinarily found to be one of chronic passive congestion of the cellular tissue, rather than chronic inflammation, and that hemorrhage resulting from the operation is by far the best remedy to relieve this condition, an early operation seems to me to be indicated.

In cases complicated by adhesions from exudate, a different course may be followed for a time, but in those not so complicated the prolonged hot-water douches serve only to increase the congestion and aggravate the symptoms. Valuable as the remedy is in proper cases, I feel certain it has been overdone. I have used electrolysis for uterine fibroids in three or four cases within the past year, and I am quite sure it has been beneficial in reducing the size, and have but little doubt that it has controlled hemorrhage; and yet I have seen cellulitis arise from it, and fear its use unless carefully measured, so as to have it under control.

---

[1] I examined the first case July 7th, and find her in robust health and no local trouble whatever.

A SYSTEM OF DRILL FOR AMBULANCE CORPS.

By WILLIAM D. DIETZ,

ASSISTANT SURGEON, UNITED STATES ARMY.

In the regular army and in the national guard of the various States, notably New York, a great deal of interest has of late been manifested in the organization of ambulance corps. A Hospital Corps has recently been established in the army, whose members belong exclusively to the hospital department, and are not, as were hospital orderlies formerly, details from the various line organizations of the service. Besides the Hospital Corps in each company, troop, and battery of the army, four men are designated as Company Bearers, whose duty in active service is to give first aid to the injured and assist in their transportation from the battlefield. The Hospital Corps and Company Bearers are drilled by medical officers in the various methods of transportation of the wounded, and are also instructed by means of lectures in the preliminary treatment of such emergencies as may arise in the service.

A "Provisional Manual of Instruction for the Hospital Corps, U. S. A., and Company Bearers," has recently been issued to the Army Medical Department, with directions that the drill described therein be submitted to the test of practical experience, and that such modifications as might suggest themselves be noted. The drill hereinafter detailed is a modification which, to the writer's mind, commends itself on the score of simplicity.

Drill of Hospital Corps and Company Bearers.—The Hospital Corps and Company Bearers for the purpose of drill are formed as one detachment. With the tactics of said formation, mounted or dismounted, we may here dispense; suffice it to say that in dismounted drill the detachment is formed in single rank, with the Senior Hospital Steward on the right of the line, and the Junior and Acting Stewards in the line of file-closers together with the supernumeraries. Fours are counted to designate the various bearer squads. If the left squad is incomplete it may be posted in the line of file-closers.

Bearer Drill.—The detachment being in line at a halt, the instructor designates by their numbers the squads which are to be instructed in litter or ambulance manipulations. The Stewards he puts in charge of such squads as are not supervised by an officer, or assigns them to various duties in the field. An incomplete squad may be utilized as dummy wounded, or its members may be ordered to practise in transferring patients to litters or beds, or in improvised means of transportation. No. 1 of each set will be chief of squad, and will give the commands necessary to manœuvre it. The men of a squad, as soon as detailed for a specific drill, are known as *right file* (who is the chief), *right centre*, *left centre*, and *left file*.

Bearer Drill with Hand-litter Manipulation.—The chief of the squad designated to practise with a litter, procures the litter, prepares and fixes it for use, sees that the braces are securely buckled, and places it lengthwise on the ground, the end opposite and two yards in front of the centre of his squad, and then resumes his place.

The chief now commands: 1. To your posts. 2. March. At the second command the right and left centre men take position between the front and rear handles of the litter, the right centre in front, the left centre in rear, the right centre passing by the right. The left file takes position on the left of the litter, opposite its centre and one yard from it, passing by the left. As soon as the chief sees that the others have their proper posts he takes his own on the right of the litter, opposite its centre and one yard from it. All face to the front. As soon as the men have taken posts at the litter they are known as *front*, *rear*, *right*, and *left* man, according to their positions at the *front*, *rear*, *right*, or *left* of the litter.

The men having taken posts at the litter, the chief of squad commands: 1. Prepare to lift litter. 2. Lift Litter. The first command is executed by the front and rear men adjusting the braces, if any, about their shoulders, and seizing the handles; the second, by their lifting the litter in position to be carried. The right and left men stand fast. If, owing to difference in height of carriers, the litter is not horizontal, the chief of squad will direct the change in the length of the braces to correct the inequality.

He now commands: 1. Forward. 2. March. At the second command the squad step off with the left foot, the carriers marching with the litter in a position as nearly horizontal as possible, taking short sliding steps to avoid jolting and to secure a smooth and uniform movement of the litter. The side men march on their respective sides.

In case the chief desires that, in stepping off, the carriers break step, he commands: 1. Forward. 2. Break step. 3. March. At the third command the carriers break step, the front man stepping off with the right and the rear man with the left foot. The side men step off with the left.

Directed by commands: Litter right (or left); Litter half-right (or half-left); or, Incline to the right (or left); 2. March, the bearers carry the litter to its designated destination.

To halt the litter the chief commands: 1. Litter. 2. Halt; and to rest the bearers adds: 3. Lower Litter. 4. Rest. At the third command the litter is slowly and steadily lowered, and the carriers release themselves from the braces (if any); at the fourth command they stand at ease. To resume the attention he commands: 1. Squad. 2. Attention, the posts at the litter being resumed at the second command.

Transfer of Patient to Litter.—The litter having been brought up to the wounded man, the chief commands: 1. Litter. 2. Halt. 3. Lower Litter; these commands being so given as to place the litter *in front of the feet or head* of the patient (whichever be the more practicable position) in the direction in which he is lying. As soon as the litter is lowered the bearers release themselves from the braces, and the chief of squad commands: 1. To patient. 2. March. At the second command the front and rear men, who are to lift the patient, take position facing each other on opposite sides of the patient near his haunch bones, *passing by their right and left respectively*. Of the other two men, the *left* man attends to the wounded part, the *right* man attends to the litter, etc. Everything being in readiness, the chief commands: 1. Prepare to lift patient, when the carriers stoop down and pass each one hand under the back of the patient near the shoulder-blades and lock them by grasping each other by the wrist; the other hands are now passed under the upper part of his thighs and clasped. Everything being ready, the chief commands: 2. Lift Patient, when the bearers rise slowly, and when upright, at the command, 3. Forward, 4. March, they march by short steps until the head of the patient is over the pillow on which it is to rest. The chief then commands: 1. Squad. 2. Halt, followed by, 3. Lower Patient, when the bearers slowly lower the patient on to the litter.

The commands for marching and halting may be omitted, the bearers standing fast, and the right man slipping the litter under the patient. The right and left men now see that the patient is in a comfortable and secure position, the head properly supported, and the wounded part accessibly placed. The rest of the movements are executed according to the directions already given. The side men, in marching, attend to the patient's wants, safety, and comfort. If he is carried head first they will be better able to observe his features, ward off insects from his face, and protect his eyes from the sun. Should he have been carried feet first and it is desired to change his position to head first, or vice versa, the chief orders the squad to halt and lower litter. He then commands: 1. Squad. 2. About. 3. FACE, which executed, he orders the litter to be lifted and marched to the point designated. After the about face the *front* of the litter has, of course, become the *rear*, the *right* the *left*, and vice versa. Similarly, the *front* man has become the *rear* man, the *right* the *left*, etc.

To Change Bearers on the March.—The chief commands, 1. Change posts. 2. MARCH. On the second command the front and the right, the rear and the left man, exchange posts and duties, the chief, however, still retaining charge of the squad.

To Transfer Patient from Litter to Litter or Bed.—This is done in the same way as from ground to litter, the bearers always observing, as far as practicable, the rule that the head of the patient be brought to the foot of the bed or litter to which he is to be transferred, and that the direction in which the patient is lying correspond to the long axis of the bed or second litter.

General Rules to be Observed in Hand-litter Operations.—1. A litter should never be carried on the shoulders. Only the men of the Hospital Corps should be instructed in carriage of litters up and down stairs, and in the exceptional circumstances requiring raising of the litter to the level of the shoulders. 2. Crossing ditches, fences, walls, etc., should be avoided, if possible, in marching. 3. If, as in going up or down a hill or stairs, the horizontal position of the litter is impracticable, the inclination downward should be toward the feet of the patient, except in cases of fractured thigh or leg, when the head should be lowest to prevent the weight of the body from pressing upon the injured part.

Bearer Drill with Ambulance.—Under direction of the chief, the squad will march to the ambulance and be brought to a halt facing the rear of the ambulance—the centre of the squad two yards behind the centre of the ambulance. The chief then commands: 1. To your posts. 2. MARCH, when the right and left centre men stand fast, the chief arranges the interior of the ambulance and puts the litters in position, while the left file mounts the box to assist the chief and attend to the wants of patients. After completing these duties the chief and the left file resume their positions in the squad. In case the ambulance has no permanent driver, the left file will act as such. The medical officer may now inspect the ambulance, notifying the chief when the inspection is completed. On the march the squad will be two yards behind its ambulance, or the right file and right centre on the right, and the left centre and left file on the left, or all on the right or left, according to the condition of the road. When there is no immediate necessity for their services, all the bearers may be marched at the head of the ambulance column.

To Take a Litter from the Ambulance.—The chief commands: 1. Take. 2. LITTER. At this command the right and left centre men step back so as to be five yards in the rear of the ambulance, and the chief (with the aid of the left file, who mounts the box) takes a litter from the ambulance, prepares and fixes it for use, and places it lengthwise on the ground two yards in front of the centre of the squad. The chief and left file then take their positions in the squad. This done, the principles of hand-litter drill are followed, the fact being borne in mind that as soon as the men have assumed their posts on the litter they become known as *front*, *right*, *rear*, and *left man*, according to their positions at the litter. If the left file has to officiate as driver, the right man will assume, in addition to his own, the litter duties of left man.

To Load the Ambulance.—The litter is halted and lowered by appropriate commands, so given that the head of the patient will be toward and close to the rear of the ambulance. If the patient has been carried head foremost, the squad will be facing the rear of the ambulance when the litter is lowered, and the chief of squad then commands: Prepare to load. But if the patient has been carried feet foremost, the squad will be found facing away from the rear of the ambulance when the litter is lowered in proper position; hence the chief, before directing: Prepare to load, commands: 1. Squad. 2. About. 3. FACE, which being executed he commands: Prepare to load, as in the previous case. It is to be again noted that when the about face is executed, the rear of the litter becomes the front, the left the right, the rear man the front man, the left man the right man, and vice versa.

At the command, Prepare to load, the *right man* takes post at the *right front handle* of the litter and faces the litter, the *left man* takes post at the *left front handle* and faces the litter, the *rear man* remains between the *rear handles*, and the *front man* mounts the *box*. All being in readiness, the chief commands: 1. Raise litter. 2. PASS IN. At the first command the bearers stoop, take hold of the handles, and slowly raise the litter to the level of the rollers on the floor of the ambulance, being careful to keep it in a horizontal position. At the second command, the front handles of the litter are slowly and gently placed on the rear rollers and passed in, the man between the rear handles pushing and following the litter, halting and occupying the space between the men at the front handles. During this operation the men at the front handles attend to the folding of the litter legs, and the man in the ambulance sees that the litter fastenings are properly adjusted. Should there be but three bearers with the litter—one having remained with the ambulance as driver—the front man takes the vacant space at the side of the litter when the order, Prepare to load, is given.

To Unload the Ambulance.—The men of the squad being at their posts in rear of the ambulance, the chief commands: Prepare to unload. At this command the *right file* places himself at the *right* and the *left file* at the *left* of the litter to be withdrawn, both facing in, the *right* centre man loosens the litter fastenings *in the ambulance*, the *left centre* man steps *between* the *handles* of the litter to be withdrawn. If there be but three men to unload the ambulance—one of the bearers officiating as driver—they will take position around litter to be withdrawn as indicated, viz.: the right file of the three to the right, the left file to the left, and the centre man between the handles. All being in readiness, the chief commands: 1. Pass out. 2. LOWER LITTER. At the first command the man between the handles takes hold of them and draws out the litter, the men on the right and left stand fast and support the poles until the front handles are reached, and adjust the litter legs properly. Care should be taken to preserve the horizontal position of the litter at the level of the rollers. At the second command, the litter is slowly and steadily lowered to the ground.

The patient having been carried to his proper destination, the squad will return the litter to the ambulance, and unload the other, if required, after which they will break ranks, or will fall in line and await further orders.

Bearer Drill with Arms and Horses.—In case the bearers are encumbered with rifles, the latter will be carried by the side men. When a patient is to be transferred from the ground to a litter, the left man, who attends to the wounded limb, turns all the guns over to the right man, who is responsible for their safe keeping. When the patient is being carried, the side men will take the guns as before. Before loading the patient into the ambulance, the rifles must be stacked. If the squads are mounted, they will dismount, and the left file of each squad will take charge of the squad horses. In the litter drill the three men will operate on foot as above indicated, the single side man performing the duties of two side men. In the ambulance drill, the three men will operate as already detailed, the ambulance having a permanent driver. In manœuvres in improvised methods two squads may be combined, the left file men taking charge of the horses, while the others, as a squad of six, operate under direction of the medical officer.

In conclusion, the writer desires to express his indebtedness to the Provisional Manual of Instruction, but is of the opinion that, by discarding numbers in his drill, he has simplified the rules for transfer of patient from ground to litter, and for the loading and unloading of the ambulance. In the bearer drill with ambulance, he is thus enabled, under "Prepare to load," to give a rule which (unlike that of the Manual) holds good whether the patient has been carried head or feet first, or whether the bearers have or have not changed posts on the march.

REMOVAL OF THE UTERINE APPENDAGES, WITH UNFAVORABLE SEQUELÆ — TWO ILLUSTRATIVE CASES.

By D. TOD GILLIAM, M.D.,

PROFESSOR OF OBSTETRICS AND DISEASES OF WOMEN, STARLING MEDICAL COLLEGE, COLUMBUS, O.

THE wonderful impulse given to abdominal surgery in the last decade, and the phenomenal success attending it have led to such a multiplication of cases and such a diversity of features as to cause the exclusion of detail in all except the most remarkable. The result is, that announcements of successful cases are usually supplemented by the simple remark that the patient made an uninterrupted recovery, while, on the other hand, unsuccessful cases, when reported, at all, are given in full. Hence, to one not entirely conversant with the run of such cases from a large and varied experience, any untoward symptoms that may arise in the course of a case in hand are invested with an ominous significance, simply because he has been accustomed to find them associated with the unsuccessful cases. This often gives rise to a great deal of mental distress to the one having such cases in charge, and reflexly to the patient and friends. Much of this may be obviated by a proper interpretation of symptoms. It occasionally happens, also, that operations are done at a distance, and the patient left in charge of a local physician, who feels keenly the responsibility of his charge, and seeks in the books and medical journals those details which his lack of personal experience renders necessary. It is the knowledge of a case of this kind, wherein the physician in charge put in many anxious hours ransacking books and periodicals for the interpretation of certain symptoms, and which, after all, he could only find in the history of unsuccessful cases, that actuates this communication.

In dealing with cases of abdominal section the rule of prognosis, as enunciated by Tait, should never be lost sight of, which is, in effect, that the temperature taken alone is of little significance, but, on the other hand, the pulse is the true index of the patient's condition.

Tait avers, and I have found it to be the case, that a thermal excursion of from 4° to 6° F. is not infrequent after abdominal section, and is of itself comparatively unimportant. If, however, the pulse be rapid and thready the prognosis is affected accordingly. In cases running to a fatal issue the pulse-rate *progressively* increases until, as Tait very aptly expresses it, it runs out. A pulse, however, that varies from time to time, being now fast and now slow, is not of the same gravity, although a very rapid pulse, unless plainly of nervous origin, is always a source of anxiety.

I append the history of the two following cases, taken from my note-book of the current year, not because they are unique, but for the opposite reason that they are representative of a class of such cases as do not make an uninterrupted recovery.

CASE I.—Mary McC——, aged thirty-five, married, sterile, a long sufferer from ovarian dysmennorhœa of the most aggravated type, had been under treatment at Philadelphia and Pittsburg, respectively, without avail. At both places, according to her statement, the removal of the uterine appendages was discussed but abandoned. She was practically a wreck in that she was incapable of physical exertion, was compelled to forego the marital relation, besides being a constant sufferer. On examination I found a very firm mass occupying the cul-de-sac, and extending to the left, which was fixed and very tender. To this I gave the interpretation of inflammation and agglutination of the uterine appendages, and in its firmness and fixation found, as I thought, an explanation why the operation had not been undertaken before. The patient was importunate, however, and, having been prepared, I made an exploratory incision. The parts were matted and unrecognizable, the mass being exceedingly firm. Notwithstanding, I proceeded with the operation, and after an hour and a half's hard work succeeded in disengaging the greater part of both tubes and part of the left ovary. At this stage I was compelled to abandon further effort, and the patient, after thorough cleansing, and the introduction of a glass drainage-tube, was put to bed profoundly collapsed. Under external and hypodermic stimulation she rallied very slowly, complaining of great pain, and soon commenced to vomit, which she kept up for seven days. Her temperature ran up and down through an arc of four degrees, and the pulse varied from time to time, but at no time got above 135.

The glass drainage-tube seemed to annoy the patient greatly, and with its withdrawal, on the seventh day, a marked improvement was at once noticeable. After this her recovery was slow and uneventful, convalescence being retarded by stitch-hole abscesses and a purulent discharge from the tube-tract. Three months subsequently she was happily engaged in her household duties, had resumed her marital relations, and was *menstruating* painlessly. The above is one of those instances in which even an incomplete operation broke the chain of morbid action, and restored the patient to health. Instances are not wanting in which a simple exploratory incision has redounded greatly to the benefit of the sufferer.

CASE II.—Ida M——, aged twenty-seven, single, menstruated at thirteen, had retroversion at sixteen, had partial hemiplegia at same age, and chorea six months later, which continued two years and then improved. Two years ago last August the symptoms became worse, and she had an epileptiform convulsion, since which time these attacks have been growing in frequency and intensity. Convulsions are preceded by a pain and immobility of the right arm and right side of the tongue, and, as she says, can be stopped by standing on her head. If not thus prevented, unconsciousness gradually supervenes. She thinks the uterine supporter, which she wears constantly, when properly adjusted, prevents the convulsions, as in its absence they are much more frequent. By nature bright and vivacious, she is gradually lapsing into fatuity, and has become morose and irritable. I saw her first on July 26th, and found the uterus partially retroverted and heavy, both ovaries occupying the cul-de-sac, large and tender, but not adherent. Pressure on the ovaries gave rise to the prodromes of convulsive seizure, but was not carried to the extent of provoking one. When told that the removal of these appendages might be necessary to a cure, she eagerly accepted the alternative, and said her physician had sent her to me for that purpose. Menstruation being imminent, I deferred the operation until the next intermenstrual period, but was compelled to operate on the fourth day after the flow had ceased.

Accordingly, on August 6th, at 10 A.M., the ovaries and tubes were removed without difficulty any further than, the abdominal walls being thick and the pedicle short, it was almost impossible to bring the parts to light for ligation. In transfixing the pedicle I suppose a vessel was punctured, which, not being discovered at the time, gave rise to a small but persistent hemorrhage. She was put to bed in good condition, the drainage-tube being inserted on account of the bloody suping.

At subsequent visits it was found that the patient slept much of the time, but was restless and anxious when awake. The tube at each visit was found filled with bloody serum, and was as often washed out. The pulse ran from 99 on the evening of the first day to 120 on the second, 116 on the third, 98 on the fourth, 110 on the fifth, after which it, with many variations, gradually dropped to the normal. The temperature varied from the normal to 102° F., which latter temperature occurred on the evening of the fourth day. On the morning of the third day I found that she had got at and withdrawn the drainage-tube, and was more comfortable and cheerful, though apprehensive lest I should reprimand her. In this as in the other case, the tube was a source of great discomfort to the patient, and I concluded to leave it out. At 1 P.M., pulse 116, temperature 100.8° F., face flushed, expression anxious, complains much, gets only cat-naps, abdomen tender and tympanitic. She has a sanguineous flow from the vagina, equivalent to a normal menstruation. I ordered tablespoonful doses of salts in hot water every three hours, using mustard over the stomach to insure retention. She has vomited once or twice daily since the operation. I had in mind to open up and irrigate in case this did not relieve. At 8 A.M. next morning I found her looking and expressing herself much better. Four doses of salts had been given, one of which was rejected but immediately repeated. No action of the bowels. Pulse, 98; temperature normal. Abdominal distention much abated; dressing not soiled, and therefore not changed. A serous transudation had, however, set in toward the bowels, as she during this day had numerous liquid defecations. From this time on the case ran evenly, and on the sixteenth day the wound was healed. She has had no recurrence of her former trouble, and is now being weaned from her accustomed nervines and stimulants. On examination of the ovaries no corpus luteum of menstruation was to be found in either, notwithstanding she had just emerged from the menstrual period, thus giving additional support to the tenure that menstruation and ovulation are independent processes. Several large follicles were observed in both ovaries, one of which was apparently about mature. I will take this occasion to say that I have about concluded to abandon the use of the drainage-tube altogether, and instead, when drainage is indicated, to leave an open way into the abdominal cavity by the use of two strips of sheet-lead, one on either side, which can be easily separated, and a flexible tube introduced for purposes of irrigation.

ARTERIAL CHANGES IN PHTHISIS.—Dr. Pina has examined microscopically the arteries in ten young subjects who died of phthisis in Professor Manassein's wards in St. Petersburg. The results noted were very constant, and are thus briefly described in a "preliminary communication" published in *Vrach*. The arterial changes were generally identical with those of chronic fibrous endarteritis. Connective tissue was found in the inner coat of vessels where in a normal condition it does not exist—the brachial, the radial, the ulnar, the femoral, the popliteal, the anterior tibial, the temporal, and the coronaries of the heart. Again, in arteries where the intima ordinarily contains connective tissue the amount was very markedly increased. The greatest and most important modification was found in the coronaries, in which the layer of connective tissue in the internal coat frequently occupied the whole field of the microscope. The changes were least marked in the middle of the brachial, in the arch of the aorta, and in the pulmonary arteries. In the middle coat atrophy of the muscular fibres was found, together with connective tissue, in places coexisting with changes in the internal coats, the two processes going on together. Dr. Pina does not go into the theory of the pathology, but contents himself for the present with stating facts. Further investigations are required, he says, dealing with the arterial changes in subjects who have died of other wasting diseases, and in those of a phthisical habit who have died from some other disease. The preparations made were all shown to Professors Vinogradoff and Manassein, so that the facts, as far as they go, may be taken as being well authenticated.—*The Lancet*, June 16, 1888.

A CASE OF EXTRACTION OF PARTIALLY ABSORBED CALCAREOUS LENS, COMPLICATED BY SYNECHIA POSTERIOR, WITH RESULTING VISION OF $\frac{20}{20}$.[1]

BY DAVID WEBSTER, M.D.,

NEW YORK.

ON March 15, 1888, Miss Cora C——, aged twenty-three, came to the Manhattan Eye and Ear Hospital, having been referred to Dr. Agnew and myself by a New York ophthalmologist.

Her left eyeball was shrunken, tender on pressure, and had, for some time, been more or less painful, while in the right eye were the chalky-looking remains of a mostly absorbed crystalline lens, with a discolored and apparently atrophic iris attached to the membranous mass behind it by strong adhesions. Vision = ability to count fingers at two feet, with good visual field.

Cora gave a history of loss of sight of her left eye from a blow of a whip-lash at the early age of two years. She saw well with her right eye up to the age of fourteen, when a painful sympathetic inflammation set in, producing cataract and causing loss of all but perception of light.

At the age of sixteen she went to Cincinnati and placed herself under the care of an eye surgeon there, who, in reply to a letter from Dr. W. H. Way, House-Surgeon of the Manhattan Eye and Ear Hospital, writes as follows: "The girl was then totally blind, one eye being disorganized and cicatricial, and the other cataractous. The story of the girl was that when two years old her father whipped her and injured her eye. Afterward the other got inflamed and became blind. When she entered the clinic she could not go from one room to another without a guide. After an operation and six or eight weeks' treatment she could see enough to take care of herself, distinguish colors, etc. The cataract was liquid (soft) and was freed from its capsule with a needle sent through the cornea. The lens was like that of congenital cataract. I had no hope of the traumatic and cicatricial eye," etc.

A year and a half ago a second needling was done on the right eye by a Buffalo eye surgeon, by which the sight was considerably improved.

On March 16th Dr. Agnew enucleated the atrophied eyeball, and, upon opening it, found a small calcareous lens, and in the choroid a large calcific plate. While the patient was still under ether he performed an iridectomy upon the right eye, removing a portion of the iris outward and slightly upward, that being the direction in which the pupillary margin seemed most free from adhesions.

March 24th.—There has been very little reaction in the right eye, and the stump of the left is healing kindly.

March 31st.—The patient is doing well. Dr. Agnew says he will not be in a hurry to operate on her again.

April 27th.—Having dropped in cocaine and cleansed the eye with a solution of the bichloride of mercury, I introduced a Knapp's knife-needle and severed two or three of the adhesions, one of which, in the form of a string, was in such a state of tension that when cut it separated with an audible snap. Before withdrawing the instrument I tried to puncture the pupillary obstruction with it, but so tough was the mass that it receded before the point of the knife-needle, and I had to withdraw it without having made an opening in the cataract. There was considerable blood effused into the anterior chamber from this operation.

April 28th.—The blood has been absorbed from the anterior chamber. There has been very little pain or reaction.

May 14th.—Having placed the eye under cocaine I made a small opening through the cornea, near its nasal periphery, with a Graefe's knife, introduced a sharp hook, and caught the membranous mass by its temporal border and tried to draw it out of the opening, but the membrane was too thick to come out of so small a wound, and so slipped off the hook and was left behind.

---

[1] Read before the American Ophthalmological Society on July 19, 1888.

May 22d.—The eye has improved constantly, there being some partially clear pupillary space.

June 6th.—Having again thoroughly anæsthetized the eye with cocaine, I made a wound at the supero-nasal border of the cornea, as for iridectomy, using a keratome bent on the flat, and introducing a pair of back-toothed iris-forceps. I seized the infero-temporal border of the cataractous mass, and turning it over on itself pulled it out of the eye, and putting it on the stretch cut it off with scissors close to the cornea. The attached portion of the mass receded, leaving a clear pupil. No vitreous escaped. This operation was followed by some pain, lasting several hours. On the fourth day after the operation the patient again complained of pain in the eye. It was soon relieved, however, by the application of iced cloths.

June 18th.—Fundus normal; no floating bodies in the vitreous, but the remaining portion of the pupillary membrane extends backward horizontally, and flaps up and down with the movements of the eye. This membrane was thick and tough, and probably consisted of capsule, lens matter, and plastic exudation, all of which had undergone degenerative changes.

June 22d.—Vision = $\frac{20}{20}$ W + $\frac{1}{3½}$. Reads Jaeger No. 1 with + $\frac{1}{2¼}$.

June 26th.—Discharged wearing the above spectacles.

This case scarcely needs any comment. The completeness of the history would make it interesting even if the result had not been so unexpectedly good. In all my experience, extending over nearly twenty years, I never before saw an eye whose vision had been reduced to perception of light by sympathetic inflammation have the sight restored to $\frac{20}{20}$ by operative interference.

MEDICAL CASES IN THE COURTS.

By HENRY A. RILEY, Esq.,

NEW YORK.

In a recent volume of New York Reports is found the interesting case regarding the necessity of proving the identity of a murdered person in order to secure a conviction. The case was that of Frank Palmer, convicted of the murder of Peter Bernard, in Clinton County, in 1885. Upon an appeal to the General Term the conviction was reversed and a new trial ordered. The case then went to the Court of Appeals, where the original conviction has been sustained, and the decision of the General Term reversed.

The Court of Appeals says that if the law be as the General Term has declared it, a murderer may always escape if only he shall so mutilate the body of his victim as to make identification impossible, or shall so effectually conceal it that discovery is delayed until decomposition has taken away the possibility of personal recognition; and it will follow that the tenderness of the Penal Code has opened a door of escape to that brutal courage which can mangle and burn a lifeless body, and has put a premium upon and offered a reward for that species of atrocity. The Court states that the rulings of the common law have not been changed by the Penal Code, and a number of cases are cited to show what has been the law in the past. In an old English case, cited in Wills' "Circumstantial Evidence," it appeared that a human body had been burned, but enough remained unconsumed to show that it was the body of a male adult, and its further identification was founded upon circumstances an important part of which was the finding in the possession of the defendant of numerous articles belonging to the murdered person. In a case in 3 Parker's "Criminal Reports," it appeared that a body with marks upon it had been washed ashore. It was said to be the body of Captain Palmer, for whose murder the prisoner was being tried. No direct evidence of that identity was or could be given; but the criminal fact of a death by violence having been fully established, the identity of the remains was proved by circumstances. Personal recognition had become impossible, and identity was established by an inference from resemblances. The height of the deceased was shown, an unusual length of face and a widening of the end of the little finger, to which, in a general way, the body corresponded.

But a more important fact was that the captain had imprinted his name upon his arm and leg, and, in the same portions of the body found, the skin had been cut away, except that on the leg the letter "P" remained visible. In a case found in 35 Texas, 97, there was no direct proof of the identity of the deceased, but his clothing, hat, and papers were identified, and his wagon and team, and even his dog were found in the prisoner's possession. In a North Carolina case, 7 Jones, 446, the identification was exceedingly slight, consisting merely of some articles of feminine attire found beside the bones. The general rule thus established by the common law, the Court of Appeals states, has not been changed by the recent Penal Code in this State. This being the fact, it will be of interest to know what evidence was thought sufficient to prove identity in the case under review. The Court says: "That the body found was that of Peter Bernard was established beyond reasonable doubt. The prisoner was a witness in his own behalf. He shows that he and Bernard were in the locality where the body was found at about the date of the latter's disappearance. His own declarations show that he had no doubt of the identity of the body found.

"He explains the possession of a twenty-dollar bill which in some manner he got from Bernard, but the explanation is not at all probable or satisfactory. The evidence of persons who claim to have seen the deceased after the date of the murder was probably honest, but quite certainly mistaken. He was a total stranger to them and their comparison was founded on a photograph.

"In the case of Webster there were five persons who honestly believed that they saw Parkman alive after he had in fact been killed. Upon the who lecase we see no sufficient reason to distrust the conclusion which the jury reached. The grade of crime of which the prisoner was convicted was murder in the second degree, carrying with it only confinement in the State prison for its punishment."

In a late case in a Michigan court where the crime of rape was under consideration, the defendant's counsel offered to read from "Beck's Medical Jurisprudence," but the judge declined to allow this in the presence of the jury, saying that the jury could be excused temporarily if it was thought best to present to him any argument based on the text-book. This decision was subsequently made one of the grounds for asking a new trial, but the appellate court decided that, as the medical books had not been made evidence in the case, it was not proper for counsel to read special extracts, and the decision was sustained.

A most important point in proving the crime of murder is the establishing of the fact of an intent to commit murder, and of the time necessary to form this intent. An interesting charge to the jury was given in the recent King case by Judge Lacombe of the United States District Court. Judge Lacombe is a cultivated man of wide reading and his charge shows these characteristics. He says: "As to the duration of that period no limit can be arbitrarily assigned. The time will vary as to the minds and temperaments of men and as to the circumstances in which they are placed.

"The human mind acts at times with marvellous rapidity. Men have sometimes seen the events of a life-time pass in a few minutes before their mental vision. Rear-Admiral Sir Francis Beaufort was once nearly drowned. During the brief period of apparent unconsciousness after he sank for the third time, his mind reviewed every event of his past life. His account of his experience, quoted in Miss Martineau's 'Biographical Sketches,' is very interesting. 'The course of those thoughts,' he says, 'I can even now in a great measure retrace. The event which had just taken place; the awkwardness which produced it; the bustle it must have occasioned; the effect it would have on a most affectionate father; the manner in which he would disclose it to the rest of the family; and a thousand other circumstances minutely associated with home were the first reflections that occurred. They took then a wider range; our last cruise; a former voyage and shipwreck; my school, the progress I had made there, and the time I had misspent; and even all my boyish pursuits and adventures.

"'Thus travelling backward, every past incident of my life seemed to glance across my recollection in retrograde succession; not, however, in mere outline, as here stated, but the picture filled up with every minute and collateral feature. In short, the whole period of my existence seemed to be placed before me in a kind of panoramic review, and each act of it seemed to be accompanied by a consciousness of right or wrong, or by some reflection on its cause or its consequences. Indeed many trifling events, which had long been forgotten, then crowded into my imagination, and with the character of recent familiarity.' If this mental action continued until he was fully restored to consciousness, the time consumed was about twenty minutes. Admiral Beaufort, however, was always convinced that it lasted only during submersion; if so, all these events swept before his mental vision in the space of two minutes. Thought is sometimes referred to as the very symbol of swiftness.

> "'Haste me to know't that I, with wings as *swift*
> As *meditation*, or the *thoughts* of love,
> May sweep to my revenge.'—HAMLET, Act i., Scene 5.

"There is no time so short but that within it the human mind can form a deliberate purpose to do an act; and if the intent to do mischief to another is thus formed as a deliberate intent, though after no matter how short a period of reflection, it none the less is malice. Malice in the old definitions is spoken of as express or implied. That, again, is a distinction which is a delusion and a snare. Practically, jurymen never deal with express malice. There is no express evidence of malice given to them. Malice, as I have told you, is an intent of the mind and heart. There is never presented to a jury direct evidence of what was the intent of the man's heart at the time."

It may be remembered that not long since, in this journal, I made reference to an interesting case in a New Jersey court, which held that an undertaker's establishment, in a well-settled part of the city of Camden, could not necessarily be considered a nuisance *per se*, and that there were no special circumstances connected with the particular establishment which entitled it to the interference of a court of equity. A somewhat similar case has recently been before the Florida Supreme Court. The counsel for the complainants argued that a livery stable closely adjoining a hotel could not be otherwise regarded than as *prima facie* a nuisance. But the Court decided against this view, and said: "It will be found that the cases in which livery stables have been held to be nuisances, either in equity or at law, are cases where the proof established the fact; in some instances the Court withholding their final decision until the fact could be tested by actual experience. It is not to be understood that this conclusion involves a decision that the stable may not become a nuisance. The complaint as to noise from the stamping of horses, if the wooden floor is taken out, as the answer says it will be done, is removed; and there only remains the question whether, from noisome smells or other discomforts produced by the use of the stable, there will arise a case for the interposition of equity. While it is easy to anticipate disagreeable results, it cannot be said, as a matter of fact, that these will necessarily follow to the extent of a nuisance. Considering the improved methods of the day, the dealing with various offensive appurtenants in and about dwelling-houses and hotels, so that little discomfort is experienced, it is not unreasonable to suppose that proper appliances in the management of a livery stable may produce similar good results."

Questions concerning the liability of owners of cattle suffering from contagious diseases, for misstatements in regard to their condition, are occasionally before the courts, and, in a recent case in Missouri, cattle were sold which had the Texas fever. This disease is not easily detected except by those familiar with it, and the point raised was whether the seller must refund the price. It was held that the concealment was a fraudulent device on the part of the seller and that the usual maxim of *caveat emptor* did not apply. In another case the action was for fraud in the sale of an unsound horse. The Court had instructed the jury that if the buyer relies upon his own judgment and observations and the seller makes no representations that are untrue, or says nothing, the buyer takes the property at his own risk. This instruction was held to be erroneous, the Court saying, if the seller knows of a latent defect in the property that could not be discovered by a man of ordinary observation he is bound to disclose it.

In a case in New York State a flock of sheep were sold and they afterward turned out to have the disease called "scab." Here it was said that if the defendants knew that the sheep were diseased it would have been their duty to have informed the purchaser.

In another case, a horse was sold which was unsound from the loss of teeth, but this was also held to be a latent defect which would ordinarily have escaped the attention of buyers of horses, and the concealment was a fraud upon the purchaser.

A CASE OF SUPERFŒTATION.—Mr. James Arthur, of Durham, England, writes to *The Lancet*: "On May 23d I was called to Mrs. D——, aged twenty-six, in her fourth confinement. The vagina was occupied by a large bag of membranes, which I immediately ruptured, and found two feet presenting. While preparing to grasp them, my attention was drawn to a small body between the two feet, and about the size of one of them. It seemed to loosen its attachment, and came away without any force. Thinking it might be a polypus, I laid it aside and proceeded with the labor, which was easy—a seven months' child, and nothing unusual about it. On getting a light (it was then late, and delivery had been performed almost in the dark), I found the small body to consist of a perfect fœtus of not more than eight weeks, with two inches of umbilical cord attached. It was much flattened transversely, judging from its position, owing to pressure between the other child and the promontory of the sacrum. Unfortunately, the placenta was removed before I had time to examine it and ascertain if there were two. The mother had no sanguineous discharge whatever during the period of gestation. A friend to whom I showed the specimen suggested blighted conception of one twin, but this is negatived by its fresh and perfectly normal appearance. I have no literature on the subject, and, being in the country, have no opportunity of consulting any."

A STOMATOLOGICAL SOCIETY has been established in Paris, the object of which is the scientific study of diseases of the mouth, including those of the teeth and alveolar processes. The head is now fairly well filled with specialties, but as the Society of Stomatology has neglected to include the tongue and the lips specifically among the subjects of its study, we may yet hope to see glossological and cheilological societies spring up in the near future.

Progress of Medical Science.

On the Functions of the Uvula and Epiglottis.—Dr. Spicer has published a paper on the functions of the uvula and epiglottis (*The Lancet.*) The various functions of the uvula in deglutition, phonation, articulation, respiration, and secretion, as set forth by different authorities, are discussed, and then the author describes an important function which had hitherto escaped detection, namely, that the uvula served during normal (nasal) breathing as a conductor, guide, or dripping-stone to convey the nasal and lachrymal secretions out of the breathway on to the lingual tonsil, there to undergo reabsorption into the circulation. These fluids were delivered on to the base of the tongue in a plane anterior to the epiglottis. From the lingual tonsil the unabsorbed portions trickled into the glosso-epiglottic fossæ, and thence into the pyriform sinuses or hyoid fossæ, along the lateral grooves of the epiglottis. It was mentioned that two previous authors had considered the uvula as a conductor or dripping-stone to convey mucus, etc., into the larynx for lubricating purposes, or to the base of the glottis, where it is accumulated until swallowed or hawked up. Common experience taught us that such intrusion of fluids into the larynx as was assumed, caused cough and spasm ; these views were hence, in part, the antithesis of the one expounded. The functions of the epiglottis were next considered, and it was pointed out that the balance of evidence was against any deglutition function of the epiglottis, but in favor of its movements and position having an important connection with the pitch, intensity, and the quality of the voice. The author described the epiglottis as a permanent vaulted dam, which kept the salivary fluids, etc., as well as those conducted by the uvula from the nose, out of the larynx, and which shot them off laterally (if not absorbed by tonsillar tissue) into the pyriform sinuses along the grooved spouts of the epiglottis, which projected over those sinuses normally. Clinical observations and experiments bearing on these views, and tending to show their correctness, were given in detail.

Suprapubic Cystotomy.—Dr. Eigenbrodt has published an elaborate study of this subject, of which the *American Journal of the Medical Sciences*, August, 1888, contains the following résumé : Inflation of the rectum by the rubber bag is not advised, as the peritoneum is readily avoided without such a procedure, and as the method is not devoid of danger. When the suprapubic percussion-dulness of the full bladder can be recognized, no more fluid need be injected. Over-distention is never necessary, nor previous treatment of cystitis or contracted bladder. The incision should be transverse ; if extensive, slightly convex downward, so that the extremities may correspond in direction with the inguinal canal. On reaching the deep fascia and abdominal muscles, it is most important to continue the operation as close to the pubic bone as possible, operating as though the object in view were the cutting away of the soft parts from the upper and posterior portion of the symphysis. Trendelenberg, by pressing with the fingers of his left hand against the sheath of the exposed muscles, so stretches their attachments to the bone that a touch of the knife frees them, and the danger of wounding the deeper-lying soft parts is avoided. A few muscular fibres of the pyramidales are divided, but the two recti are not wounded.

The extent to which the fasciæ and tendons are separated from the pubis depends upon the room required for subsequent manipulations. For the extraction of an ordinary stone, an incision one and one fourth to one and three-fourths inch in extent is sufficient. For tumor operations, or the removal of very large stones, two and a half to three and one fourth inches will be required, and both recti will be completely separated from the pelvis. The fasciæ and tendons having been cut from the pubes, the prævesical cellular tissue is exposed, usually containing much fat. The knife must now be laid aside, the second and third fingers of the left hand thrust in the prævesical space, dorsal aspect to the bone ; the index and middle finger pressed down well behind the symphysis till the region of the neck of the bladder is reached, then bending the fingers, all the soft tissues lying anterior to the bladder, especially the peritoneal fold, are drawn carefully upward ; the bladder is now exposed, and can be safely incised, the fingers of the left hand readily keeping the peritoneum out of the way. Tenacula are by this procedure unnecessary. If a very large incision into the bladder is required, the peritoneum can readily be separated from that viscus for a considerable extent with the fingers. In the manner described, even a bladder which has not been injected is, in a few minutes, exposed and safely opened. Elevation of the pelvis greatly simplifies the operation, and in this position the patient should always be placed. After the completion of the operation, the bladder is thoroughly washed out with a weak sublimate solution (1:3000 to 5000), a T-formed drainage-tube is placed in the bladder, carried over the symphysis, through the central portion of the external wound ; the extremities of the superficial incision are closed by a few sutures passed through the skin, and iodoform gauze is loosely packed in the open wound about the drainage-tube. If the superficial incision has been extensive, drainage should be provided for at both extremities of the wound. If a very large bladder-incision has been made, a few sutures may be inserted to lessen the size of the wound, but complete closure by suture is not yet justified by statistics. Suturing of the bladder with loose antiseptic packing of the parietal wound, as advised by Kraske, Ultzmann, and Mikulicz, is yet *sub judice*. Trendelenberg removes his drainage-tube in from one to two weeks ; in uncomplicated cases three to four weeks sufficed for a complete cure. In cases of marked cystitis or pyelitis with alkaline urine a long-standing fistula results, lasting, at times, if the condition of the urine be unchanged, for life. In Trendelenberg's cases there was no instance of urine infiltration or cellulitis. In one case only was there burrowing of pus—the patient, a feeble old man, dying of exhaustion thirteen weeks after the operation.

Of Trendelenberg's thirty-eight patients seven died in the course of treatment. No death can be ascribed directly to the operation. Three perished of intercurrent disease more than one month after the operation, two of carcinoma (four and five days after the operation respectively), one of delirium tremens (twelve months after operation), and one of burrowing of pus and profuse suppuration (two months after operation).

Against König's dictum, "The perineal incision must remain the natural operation for the lighter cases, the more dangerous high operation being reserved for the severe cases," the author contends that before operation it is often impossible to tell how difficult the case may be, and shows by reference to Trendelenberg's cases several instances in which history and examination would have proven the case amenable to the median operation. The conditions on opening, however, proved that none but the high incision could have carried the patients safely through. All of Trendelenberg's uncomplicated stone cases made a safe and rapid recovery ; and Assendert, who has done the high operation one hundred and two times, lost but two patients, one from causes not connected with the operation. All of his patients were young. The high operation takes its place as beyond all other procedures in the treatment of diseases of the bladder-walls. All of Trendelenberg's tumor cases were carcinomatous. If such tumors were promptly recognized and treated, a relatively good prognosis could undoubtedly be given. An early symptom is slight but frequent admixture of blood with the urine, often not observed because not accompanied by marked pain. Such bleeding, having no obvious cause, should always suggest a bladder-tumor, and lead the physician to make a most thorough and patient search for confirmation of the diagnosis. If this necessitates an operation, the high incision should be made at once, when, on confirmation, the operator can proceed directly to extirpation. This should be accomplished with scissors and sharp spoon, or by excision of a part of the bladder-wall; bleeding being stopped by cautery. Tubercle of the bladder gives rise to symptoms much like those of tumor, and can often be diagnosed only by visual inspection after opening the bladder. The high operation alone enables the surgeon to do this satisfactorily and undertake the radical extirpation of the diseased areas. Finally, the high operation is commended as most suitable for posterior catheterization, when, through traumatic stricture with great periurethral inflammation and cicatrization, or false passage with infiltration, or rupture of the urethra, the ordinary means of procedure (ordinary catheterization, the median operation, etc.) are no longer available.

SIMPLIFIED ANTISEPSIS.—The present tendency of surgery is undeniably in the direction of doing away with the unnecessarily cumbersome apparatus of ultra-antisepticism. Professor Kocher, of Berne, has even gone so far as to demand that catgut be discarded altogether, since its use may be followed by unpleasant results. Sterilized wounds are the modern chirurgical desideratum. Kocher accomplishes his object of securing asepsis about as follows:

1. The ceiling, floor, and walls of the operating-room should be thoroughly washed with soap and water and dried. Then three tables, carefully cleansed in the same way, should be brought in. One of these is to serve as the operating-table, one to hold the instruments, and one to hold the various other utensils. 2. A half-dozen thoroughly-cleansed and boiled bowls and basins should be on hand to hold the antiseptic solutions, also some bottles for the same purpose, and a large quantity of hot water, which must have been boiling two hours previously. 3. Soap and brushes are to be ready to wash and scrub the skin, hairs, and hands of all who take part in the operation. Also large sheets of impermeable material to cover the patient, the instruments, and the bandages. 4. For the preparation of the antiseptic solutions a quantity of concentrated solution of carbolic acid in a measuring-glass and a sufficient quantity of sublimate are needed. 5. Besides the instruments, there should be a glass containing glass drains in one-per-cent. solution of sublimate, and another vessel of the same solution containing fine silk-thread wound on glass spools, sponges in a five-per-cent. carbolic-acid solution, and, finally, a large quantity of unprepared bandages, lint, and gauze.—*Correspondenzblatt für Schweizer Aerzte.*

THE TREATMENT OF FIBRO-MYOMATA COMPLICATING PREGNANCY AND LABOR.—According to Dr. Phillips fibromyomata may induce labor, cause peritonitis, obstruct the passage of the fœtus through the pelvis and cause fœtal malpositions. The placenta is often adherent to the tumor; uterine contraction and involution are interfered with, and the disintegration of the tumor may cause sepsis.

Fibro-myomata in the body of the uterus disturb pregnancy. These tumors, when in the lower uterine segment, may ascend; when in the cervix fibro-myomata impede delivery.

Phillips has found three hundred cases collected by Lefour; he adds fifty-nine cases in which the tumor complicated pregnancy or labor in which laparotomy was not performed, and forty-seven cases in which it was.

Before the fœtus was viable, abortion was produced in four cases, which recovered. Myomotomy (abdominal section and removal of fibroids by ligature) was performed five times, with two recoveries; this operation is indicated when the tumor is accessible, and causes great pain by distention. Müller's ablation (abdominal section, with removal of tumor and uterus) was performed nineteen times, with twelve recoveries. The stump was treated extra-peritoneally in thirteen cases, with nine recoveries; intra-peritoneally in six cases, with three recoveries.

During fœtal viability labor was induced nine times, with three maternal and seven fœtal deaths. Playfair reports three cases in which the tumor was successfully pushed up during labor; others have not been so successful. Mundé removed successfully a large cervical fibromyoma *per vaginam* during labor.

Phillips has collected thirty-three cases of Cæsarean section for this complication, up to 1880, with a maternal mortality of 84.8 per cent. Since 1880 there have been thirteen Cæsarean operations and thirteen Porro operations *with equal maternal mortality*, 69.22 per cent.; the fœtal mortality was slightly less by the Cæsarean operation. The mortality rate by Müller's ablation was 36.8 per cent.

The statistics of Lefour's cases show that the forceps, embryotomy, version, and spontaneous birth resulted in maternal mortalities from twenty-five per cent. to fifty-five per cent.; fœtal mortality averaged seventy-seven per cent.—*The American Journal of the Medical Sciences.*

MENTHOL IN SURGICAL PRACTICE.—Dr. Girard, of Berne, Switzerland, claims very good results from a mixture of equal parts of menthol and iodoform, in the form of a dry powder, in fourteen cases of scraping out and resection of tuberculous bones and soft parts, the wound being either rubbed or plugged with the powder. In every instance the wound healed more rapidly and kindly, and generally the whole course of the case seemed to be more favorable than in another series of similar cases where iodoform alone was employed. As far as Dr. Girard's personal experience goes, menthol causes but trifling local irritation and pain, while it is said to be the best deodorizer in regard to iodoform.

DOUBLE NEPHRO-LITHOTOMY.—At a meeting of the Royal Medical and Chirurgical Society (*The Lancet*), Mr. Herbert W. Page read a case of double nephro-lithotomy, in which lateral and median lithotomy had been previously performed, with remarks on sympathy between the kidneys. A man, aged twenty-two, entered St. Mary's Hospital, in November, 1886. For ten years he had suffered pain in the region of the left kidney, with occasional attacks of left renal colic. In 1882 he began to pass gravel and to suffer from irritability of bladder, and in 1885 a small calculus was removed from the bladder by lateral lithotomy. Symptoms of vesical calculus soon recurred, together with pain in the left loin, and his general health became much broken. His urine contained pus and occasionally blood. Left calculous pyelonephritis was diagnosed in addition to stone in the bladder, and this was accordingly removed by median incision on December 4, 1886. On the 15th the left kidney was exposed in the loin and two small calculi were removed from a large suppurating cyst. The amount of pus, however, did not materially lessen, and towards the end of January he began to have pain in the region of the right kidney, from which it was soon suspected that the pus now came. On February 18th he was attacked with violent pain in the right loin, with rigors, vomiting, and high temperature. At the same time the pus almost entirely disappeared, and his urine dropped from forty-two to twenty ounces. It was believed that this urine was furnished by the left kidney only. The symptoms increased and there was fulness in the right loin. On February 25th the right kidney was exposed; it was found much enlarged and surrounded by fetid pus, and there was an opening into the pelvis from which an abscess had probably burst into the perinephral tissue. No stones were found. He did well after this operation. The urine steadily increased in quantity, the pus diminished, and his pain ceased. He left the hospital on May 26th, and a few days afterward he passed four small calculi per urethram. From that time he made steady progress toward recovery. The case is of interest from its bearing on the question of sympathy between the kidneys, and it was suggested that in this case the right kidney had in all probability contained calculi, though without giving rise to symptoms, for some considerable time, and that its condition was revealed by the operation on its fellow. In support of this view the author referred to a case recently under his care in which the presence of calculi was first made known after the operation of hysterectomy, undertaken by the late Dr. Meadows. Reference was made to other cases in which there was a somewhat similar sequence of events. From another point of view, Mr. Page considered this case of importance in its bearing on nephrectomy and preliminary abdominal exploration. Nephrectomy, as time proved, would have been in this case a very wrong thing, but he had never felt quite satisfied that abdominal exploration, by which he would have found an apparently useless left kidney and a right kidney so enlarged as to be presumably fit for all future needs, its calculi being, moreover, so small as to elude detection, might not there and then have led to nephrectomy. The patient would have been placed thereby in a position of infinitely greater danger when at a future day the right kidney was in its turn *hors de combat.* The case thus demonstrates with how many precautions and with what consideration abdominal exploration for the examination of kidneys must be made.

SUPRAPUBIC PROSTATECTOMY.—Mr. Atkinson, at a meeting of the Leeds and West Riding Medico-Chirurgical Society (*The British Medical Journal*), gave an account of two cases in which he had removed portions of the gland by Mr. McGill's process. In the first case a farmer, aged sixty-six, was admitted to the Leeds Infirmary with a five-years' history of repeated attacks of retention, requiring catheterism, the urine drawn off containing blood. The last attack occurred two days before admission. The bladder was much distended; there was a free urethral hemorrhage, and the prostate was much enlarged. A catheter drew off dark chocolate-colored urine with numerous clots. The urine was regularly drawn for eight days and the bladder irrigated. The rectum was distended by a bag containing twelve ounces of water, and the bladder injected with ten ounces of boracic solution, and opened over the pubes. A growth about the size of a cricket-ball was found to spring from the right lobe of the prostate. There were two openings into the bladder, one below and behind the growth, the other, which seemed to be a false passage, through the centre. The mucous membrane being incised, a considerable portion of the growth was enucleated in several portions. There was free hemorrhage, and the patient's condition caused some anxiety for a few days after the operation on account of vomiting, diarrhœa, and great weakness, but he made a good recovery, and was discharged well twelve weeks after the operation, passing urine freely by the natural passage.

CASE II.—A man, aged seventy-one, had had symptoms of enlarged prostate two years and retention for four days before admission. The bladder had not been emptied for two days and was much distended. A catheter withdrew fifty ounces of deeply blood-stained urine. After six days of regular catheterization and irrigation of the bladder with astringents without restraining the hemorrhage, turpentine was administered successfully as regards the hemorrhage. The bladder was opened, and two large masses were found projecting into the viscus on each side of the urethral orifice. A small pedunculated growth, projecting from the mesial surface of the left enlargement, was removed with scissors (this appeared to block the urethral orifice), and the two larger masses were enucleated by the fingers. There was little bleeding. The bladder was at a later period drained by a long tube into a vessel placed under the bed. The patient did well for a month, and he was allowed to get up. Six days after he was seized with acute pleurisy, of which he died. The local conditions, however, were quite satisfactory.

REMOVAL OF VESICAL TUMOR THROUGH THE MALE URETHRA.—According to the Vienna correspondent of *The British Medical Journal*, Professor Antal exhibited before a Vienna medical society a patient from whom he had removed, in June of last year, a papilloma situated at the fundus of the bladder by a modified "high operation." The wound healed by first intention, and the patient recovered. In six months after operation hæmaturia again came on, and the patient also stated that in December he noticed that small "bits of flesh" passed with the urine. In January, 1888, the patient was again admitted under Professor Antal, who found, on cystoscopic examination, that a pedunculated tumor with a nodular surface, and situated on a swollen and relaxed mucous membrane, was present near the opening of the bladder. The examination further showed that at the place from which the tumor had been removed a year previously there was only a white patch; hence there was no recurrence of the first growth. He introduced a straight forceps through the urethra into the bladder, and succeeded in tearing off the tumor, together with the pedicle. The parts of the tumor which had been thus torn off were in part removed by the forceps and in part by the catheter. Repeating these manipulations several times, the whole growth was got away. Microscopical examination of the tumor showed that it was a "papilloma fimbriatum" (Thompson). The case was interesting from the etiological point of view, as the patient had suffered from gonorrhœa and inflammation of the neck of the bladder, and the causal connection of this condition with the development of the tumor could not be doubted. This was the first case, within the knowledge of Professor Antal, in which the male urethra was used for the removal of a tumor.

INTRA-PLEURAL INJECTIONS OF STERILIZED AIR FOR PLEURITIC EFFUSION FOLLOWING PNEUMOTHORAX.—At a recent meeting of the Académie de Médecine M. Potain spoke at length on the above subject. A man in the third stage of phthisis entered the hospital with a pneumothorax, ten months ago, and to-day he is completely cured of the latter disease, and the tuberculous affection seems to have been greatly ameliorated. The man was twenty-three, and the fever, which ran high at the *début*, fell completely at the end of a fortnight. The effusion was very considerable, reaching as high as the subspinous fossa of the omoplate. Thoracentesis was clearly indicated, were it not for certain reasons which might have rendered the liquid—up to the present limpid—purulent, and consequently endanger the existence of the patient, already very precarious; as by such means the lung which had been compressed, and in this manner holding in check as it were the process of tuberculization, would, in regaining its volume, by expansion give free access to the march of the primitive malady, and the result would be fatal to the patient in a very short time. It was for these reasons that M. Potain adopted the method which he was about to explain to his colleagues. He drew off the entire quantity of the liquid, but he took care to replace it as he proceeded with air, in order to avoid the dilatation of the lung. Ten years ago such a treatment would have been considered as very rash, but it was now well known that air was only dangerous in proportion to the germs it contained, and that when deprived or purified of those germs it became completely innocuous. M. Potain performed thoracentesis in the usual manner, and introduced the air through cotton and a bottle of a strong solution of carbolic acid, which rendered it effectually sterile. The effusion returned at the end of six weeks, when the operation was renewed, the cannula used being double, to allow simultaneously the exit of the liquid and the entry of the sterilized air. Four times the operation was performed, and M. Potain thought that it was time to draw off the air and the rest of the liquid; but immediately the patient was seized with pain and suffocation, and the air had to be renewed. However, in a few weeks all trace of effusion had disappeared, the lung expanded, and the man became rapidly convalescent. Two other patients were treated in a similar manner, one of whom got well, while the other was greatly benefited.—*Medical Press.*

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place

New York, September 29, 1888.

THE SPREAD OF TUBERCULOSIS BY THE FLESH AND MILK OF DISEASED ANIMALS.

OF all the questions discussed at the Congress for the Study of Tuberculosis, held recently in Paris, the one which received the most attention was that concerning the spread of tubercular disease through the ingestion of the flesh and milk of diseased animals. It was conceded by most, if not all, of the speakers that the danger of infection through the milk of tuberculous cows is a very real one.

It is believed, indeed, that the milk is harmless, even though the cow be tuberculous, provided only that the disease have not invaded the mamma. But when it is remembered that the diagnosis of tubercular mastitis in the cow, in its early stages at least, is very difficult, if not impossible, it will be seen that this belief offers but little assurance of safety. Furthermore, the milk supply of cities is almost always a mixture of the milk from a large number of cows, and the presence of one diseased animal in the herd is sufficient to infect the entire product of the dairy.

This subject is one that has only recently attracted much attention, but that it is of vital importance needs no argument to demonstrate. Most of the laity, however, and even many physicians, do not yet appreciate its gravity, and we feel that the Congress has done good service in emphasizing the danger of infection from raw milk, and in insisting upon the necessity of boiling it before it is given to infants to drink.

As to the possibility of infection from eating the flesh of tuberculous animals, there was not such unanimity of opinion among the speakers. M. Nocard, whose opinions are worthy of consideration, believed that the flesh of tuberculous animals might be eaten with impunity, provided the disease were confined to the lungs or other internal organs. Of course, the flesh of cattle with general tuberculosis should be condemned as unfit for food, but the muscular tissue, except that immediately surrounding diseased glands, of animals in good condition but with local tuberculosis, might be ingested without danger.

The views of this speaker are strengthened by the results of some experiments made by Professor Bollinger, of Munich, and published in the *Münchener Medicinische Wochenschrift*, No. 30, 1888. He inoculated a number of guinea-pigs, by intra-peritoneal injection, with the juice expressed from the flesh of tuberculous cattle, but did not succeed in a single instance in producing the disease in them. The author says, however, that he used great care in these experiments, and suggests that meat prepared for the market, even if it were itself sound, might be rendered dangerous through accidental contact with diseased tissues in the slaughter-house.

M. Nocard admitted that there was a possible source of danger in the occasional ulceration of a caseous mass and discharge of its contents into a blood-vessel. The virus is then disseminated through the tissues. The bacilli lose their vitality and are, as it were, digested in the muscles; but this occurs only after some days, and if an animal should happen to be slaughtered just after such an irruption of bacilli into the circulation, the flesh might be dangerous.

M. Arloing was the principal speaker on the side of the "contagionists." He had tabulated the results of the inoculation experiments of several observers, and had found that the disease was communicated in twenty per cent. of the cases. He calculated that an ox or cow of average size, dressed and ready for the market, weighed seven hundred pounds. Allowing half-a-pound of meat for an individual at a meal, it was thus possible to infect one thousand four hundred persons by a single animal. Of course, such wholesale infection is merely a theoretical possibility, and would never occur; yet he believed that the danger was sufficiently real to demand radical measures in the seizure and destruction of the flesh of tuberculous animals. Cooking, he said, could not be relied upon to destroy the virus, for the temperature of the inner portions of a rare roast of beef might not be over 140° F., and this was not enough to destroy the tubercle bacillus.

In view of the large business interests involved in the decision of this question, and of the fact that it did not seem yet to have been conclusively proved that the flesh of tuberculous cattle contains the bacilli of tuberculosis, some of the speakers at the Congress advised caution in the expression of an official opinion. The Congress, however, did not take this conservative view of the matter, but decided that "the seizure and destruction of tuberculous animals, whatever may be their appearance of health, should be a constant practice." To this proposition there were but three dissenting voices. One of this minority, Dr. Corrado Massa, a veterinary surgeon of Genoa, protests against this action in a letter to the *Revue Générale de Clinique et de Thérapeutique*, basing his protest on the grounds that it is impossible always to diagnose with certainty tuberculous lesions in slaughtered cattle; that even if tubercle bacilli be present, they are destroyed by cooking; and that the inhabitants of Italy already have so little beef that to deprive them of part of what they have, on the supposition that it is diseased, would be to sow broadcast the germs of misery while attempting to destroy those of tuberculosis.

It is possible that the Congress was somewhat hasty in giving its official sanction to such a radical proposition, for the question cannot yet be said to be closed. But its action will doubtless be productive of good, nevertheless, for it will give a stimulus to new experimentation, and thus we shall approach nearer to a correct appreciation of the danger to which mankind is exposed from this source.

PROPOSED YELLOW-FEVER LEGISLATION.

We are informed that a bill has been introduced in Congress offering a reward of $100,000 for the discovery of the cause and cure of yellow fever, and another for the appointment of a commission to observe and report upon the facts relative to the malady at Jacksonville, and the best method for preventing or suppressing it.

The latter bill is a wise and timely one. But a law providing for the award of a $100,000 prize for the discovery of "the cause and cure of yellow fever" is but a useless proffering of money. The cause of yellow fever may perhaps be discovered, its cure probably never. Modern science prevents infectious fevers by quarantine, disinfection, and vaccination, but a cure is not known for any of them. The wiser plan would be to take the $100,000 and place it in the hands of men capable of thoroughly investigating the disease.

THE COUNTY SOCIETY AND THE WATER SUPPLY.

We are surprised at the action of the Medical Society of the County of New York, at its recent meeting, regarding recommendations for increased water supply. Why the Society should commit itself on the question in such a way it is difficult to understand. Of course it will amount to nothing more than a useless attempt to endorse a private enterprise under the guise of a well-considered scientific opinion.

THE USE OF PILOCARPINE IN MIDDLE-EAR DISEASES.

The treatment of syphilitic and other affections of the internal ear by means of pilocarpine was recommended several years ago by Politzer. He stated that the drug was of benefit only in recent cases of these diseases, and that if no results were manifest after the lapse of eight or ten days its employment should be discontinued. He also asserted that dry catarrh of the middle ear, among other affections, was not benefited by pilocarpine. The therapeutic effect of the drug has been ascribed to the resorption of inflammatory exudation in the internal ear as a result of the increased action of the sweat and salivary glands.

In the *Archives of Otology* for June, 1888, Dr. W. Kosegarten, of Kiel, reports a few cases of aural disease treated by subcutaneous injections of pilocarpine which would seem to show that the field of usefulness of this remedy is less restricted than Politzer, and others after him, have supposed. This author was more persistent in his use of the drug, not abandoning it after eight or ten applications, and he was rewarded by obtaining good results, not only in chronic labyrinthine disease, but in dry catarrh of the tympanum. He made it a condition that the patients should submit to a course of treatment of at least six weeks' duration, injections of one-sixth grain of pilocarpine being made daily, when possible. If the treatment were well borne, and if any improvement were perceptible at the end of this time, the injections were continued, and usually with benefit.

His observations on the cases so treated led him to the belief that the favorable effect was due to a more active circulation in the tympanum, with consequent absorption of the inflammatory products and increased elasticity of the sclerosed tissues and adhesions. "It seems evident," he says in concluding his report of these cases, "that injections of pilocarpine also have a decided influence upon the mucous membrane of the middle ear, and therefore, in chronic processes of the middle ear accompanied by affections of the labyrinth, this remedy acts not only upon the internal ear, but that it can also exert a favorable influence upon the middle-ear process. By means of returning hyperæmia, which may even cause exudation, there ensues pliability of the sclerosed tissues and moistening and softening of adhesions, and in this way the unyielding conducting apparatus again becomes more capable of vibrating; where exudations had become deposited their absorption was brought about, as could be observed in the membrana tympani of a patient. The reason Politzer found the remedy inefficient in these affections was because he discontinued treatment too soon, for in these chronic processes we cannot accomplish anything except by long-continued action."

THE CRIME OF A MEDICAL JOURNALIST.

Not long ago we were called upon to record the melancholy fact that our esteemed contemporary, the *Meditsinskoye Obozreniye*, had been seized by the Russian authorities, and an entire edition confiscated, because of the publication of something that did not meet the approval of the censor. And now it is our mournful duty to chronicle a similar misfortune that has befallen the *Prager Medicinische Wochenschrift*. The editor of this journal had been rash enough to admit to its columns a letter "in which it was sought, through invective, to bring into contempt the order of the high royal-imperial governorship of Bohemia, and at the same time to incite to hatred against the State Court as regards the execution of its decrees"—or words to that effect. For this high crime the edition containing the objectionable matter was confiscated, and the editor was ordered to publish the indictment on the first page of the next issue of his journal. This has been done, and now all that remains for us is to express our regret that we should be deprived of even one number of so valuable and entertaining a journal, and to assure the editor of our deepest sympathy.

Amalgamation of the Dublin Medical Schools.—After several sittings, the Council of the College of Surgeons have agreed upon a scheme for the amalgamation of the School of the College with the Carmichael and the Ledwich. This will be submitted to a special meeting of the College for approval, and will, it is expected, meet with some opposition from those who have been "left out" in the proposed appointments. It has, of course, been found impossible to find places for all, but an effort has been made to meet such cases by compensation. Dr. Thornley Stoker will voluntarily retire from the Chair of Anatomy, and Dr. Mapother from that of Physiology—each receiving compensation.

Blue-lined Writing-paper is almost universally manufactured both in this country and Europe. The School Commissioners at Mainz have, upon medical advice, decided that the blue lines are bad for the eyes, and ordered that all school writing-paper shall be ruled in black.

News of the Week.

ECHOES FROM THE CONGRESS.—A reception was tendered to the members of the Congress of Physicians and Surgeons on Wednesday afternoon from four to five o'clock.

There was a general complaint among members of the Congress that the hotels of Washington had extraordinarily high prices and extraordinarily bad fare. It is a poor hotel man who thinks he can blind an American doctor as to the quality of what enters his stomach.

The Potomac water achieved a high reputation for its cathartic and enteralgic properties. A large proportion of eminent guests were made the victims of an interesting and probably bacillary diarrhœa. Its true nature deserves attention from the local and acclimated bacteriologists of our National Capital.

It was generally conceded by all the members of the Congress that for steady continuously gesticulated oratory the region of the Great Lakes took the palm.

The query has arisen: Since the recent Congress was so successful, why should it not come oftener than once in three years?

THE YELLOW FEVER.—At date of writing there had been 2,134 cases of yellow fever at Jacksonville, Fla., with 221 deaths. In the last four days the death-rate has been extremely low, not over two or three per cent. The fever does not seem to have reached an epidemic form at any place except Jacksonville. Some cases have occurred in a few of the smaller towns of Florida, also in Jackson, Miss., and Montgomery, Ala. The mortality from the epidemic has on the whole been comparatively slight. So far there have hardly been 300 victims.

FOREIGN VISITORS.—Among the distinguished medical men now visiting this country are Drs. William Ord, Sansom, Graily Hewitt, Pye-Smith, David Ferrier, Mr. Reginald Harrison, Mr. Victor Horsley, Mr. Durham, and Prof. Esmarch.

DR. WILLIAM C. PRYER, of New Rochelle, one of the most prominent physicians of Westchester County, died on September 24th, after a prolonged illness, at his residence in that village. Dr. Pryer was born in New York City, in 1834, and after being graduated from Columbia College, took up the practice of medicine. About 1850 he went to New Rochelle, where he remained until his death. During the war he was engaged as a surgeon on David's Island. He was a sufferer for many years from hip disease.

DR. LEWIS A. SAYRE'S CLINIC, at Bellevue Hospital, on Wednesday afternoon, was the occasion for a very pleasant remembrance on the part of the students. Mr. Reginald Harrison, of the Liverpool Infirmary, and Mr. Durham, of Guy's Hospital, London, were present and made remarks. Mr. Harrison was expected to perform a perineal section, but being prevented from so doing by the patient having a chill, he gave a very interesting and instructive description of his operation for prostatotomy, already familiar to our readers. Mr. Durham followed with the history of a unique case of pharyngotomy performed by him in Guy's Hospital for the removal of a jug-handle accidentally swallowed by a thirsty patient. Dr. Sayre, in his own impressive manner, described the early symptoms of hip-disease, as illustrated in a patient, and applied his extension-splint before the class. The case illustrated the advantage of such a mode of treatment in a striking and gratifying degree.

RECEPTION TO PROFESSOR ESMARCH.—Dr. Robert F. Weir and Dr. William T. Bull tendered a reception to Professor Esmarch at the New York Hospital on the 26th inst. It was largely attended by representative medical men from this and other cities.

A RECEPTION TO DR. GRAILY HEWITT was given by Dr. W. Gill Wylie on September 23d, at his private hospital.

CHANGES IN THE GERMAN UNIVERSITIES.—Professor Bardenheuer has succeeded the late Professor Budge, at Greifswald. Professor William Biedermann has succeeded Professor Preyer, at Jena.

A BILL HAS BEEN introduced into the Senate of the United States which authorizes the President to cause the Secretary of the Treasury (through the Marine Hospital Service) to make and promulgate such rules and regulations as in his judgment may be necessary to prevent the spread from one State or Territory to another of cholera, yellow fever, small-pox, or plague, and to employ as many inspectors and other persons as may be necessary to carry the regulations into effect. It also makes it a misdemeanor, punishable by fine and imprisonment, to violate the regulations that may be promulgated by the Secretary.

SALARIED PHYSICIANS FOR DISPENSARY SERVICE.—The Trustees of the Eastern Dispensary in this city are about to hold examinations for the purpose of filling the following positions: One Attending Physician to the Department of General Medicine, one Attending Surgeon to the Department of General Surgery and two District or Visiting Physicians. The Attending Physicians will be required to render two hours daily service at a salary of $400 per year, and the District or Visiting Physicians are to serve two and one half hours daily at a yearly salary of $500.

MURDER BY A LUNATIC.—The *Memphis Medical Monthly* states that a Mr. J. Mack Brown, and Dr. F. M. Usher, while on their way to Hot Springs, stopped at a hotel in Memphis city. While sitting quietly in the rotunda, R. A. L. Lane, a man about thirty-five years of age, walked into the hotel, went back to the rear, returned in a moment, looked over the register, turned around and walked to where Brown and the doctor were sitting, and fired two pistol-shots at the former. The manslayer then twice hissed the query: "You will have me arrested, will you?" The wounded man died almost instantly. Lane walked slowly toward a side entrance of the hotel, and was arrested. After his arrest, in reply to inquiry, he stated that his mind had been troubling him for three or four days, and that he felt he had to kill somebody. The spirits prompted him to do so. The people around him were mind-readers; they had been reading his mind, and it must be stopped. The spirits told him he must kill someone. After eating his supper, he got two pistols and walked out upon the street, intending to shoot the first man he saw. The lunatic's family physician, Dr. N. Erskine, testifies that he had sworn to the man's insanity two years before, but that he had not been committed.

THE INTERCOLONIAL MEDICAL CONGRESS OF AUSTRALASIA.—The second session of this Congress will be held in Melbourne on January 7–12, 1889. There will be sections on Medicine, Surgery, Hygiene, Forensic and State Medicine; Anatomy and Physiology; Pathology, Obstetrics, and Gynecology; Diseases of the Eye, Ear, and Throat; Psychological Medicine and Pharmacology; and sub-sections on Diseases of the Skin and Diseases of Children. The International Centennial Exhibition will be open during the session. The organizers of the Congress have exerted themselves to the utmost to make the meeting a scientific success, and have every reason to believe that it will be. A hearty interest is taken in it by all the medical societies throughout Australasia. A cordial invitation has been extended by the officers of the Congress to the members of the medical profession in the United States to visit Melbourne at this time, and to participate in the work of the Congress. Such visitors are assured a hearty welcome, and will be associated in all the work of the Congress. Application has been made to the steamship companies for special rates, and free passes will be given to visitors from abroad over all the railways in Victoria. Notice of contributions should be sent to the Secretary in time to be received on November 15th, and it is requested that an abstract of the papers to be read be forwarded at the same time. The Secretary of the Congress is Dr. H. B. Allen, of Melbourne.

THE EULOGY OF AGNEW, BY THOMAS.—Of the many tributes which have been offered to the lamented Agnew none have equalled the graceful and touching eulogy by Dr. Gaillard Thomas at a recent meeting of the Academy of Medicine. Thomas was fortunate in having such a friend, and so was Agnew. Everyone will agree with us after reading the address, now for the first time published in pamphlet form.

DR. J. M. DACOSTA, the Middleton Goldsmith lecturer for the present year, declined to receive any compensation for his lecture, and requested the New York Pathological Society to apply the amount ($100) to any purpose which might seem desirable. The matter was referred to the trustees, and they decided that the most fitting tribute to Dr. DaCosta's generosity would be to purchase some microscopes for the use of the Society, and requested the speaker to procure them. He has succeeded in getting two microscopes, one having an Abbé condenser and a one-fifth objective, the other having no condenser and being of a low power. The microscopes will be engraved with an inscription to the effect that they were the gift of Dr. DaCosta.—*College Clinical Record.*

CIRCUMCISION—It has been decided by the Jewish authorities of Berlin that in future the rite of circumcision shall only be performed by duly qualified medical men.

A STERILIZED MILK DAIRY.—A Russian doctor has established a dairy farm near St. Petersburg for the express purpose of supplying sterilized milk, free from microbes, for the use of hand-fed infants.

THE OXFORD MEDICAL SCHOOL.—The *British Medical Journal*, September 8, 1888, is pleased to observe that this great university is striving to wipe out the reproach which, but a short time ago, it fully deserved, of being a "lost medical school." In the course of last winter a lectureship of Materia Medica was established, an annual sum having been previously voted by Convocation for the salary of the lecturer. The first course was given during last summer term. The instruction given comprises lectures on the chemistry of the Pharmacopœia, besides practical work in chemical pharmacology in a laboratory which has been specially fitted up for the purpose. A most competent teacher has been found in the person of Mr. Wyndham Dunstan, Professor of Chemistry to the Pharmaceutical Society. Ever since Dr. Burdon-Sanderson went to Oxford, he has been untiring in his efforts to revitalize its withered medical faculty, and it is gratifying to see that his energizing influence is making itself felt. There is really no reason why Oxford should not be as flourishing a medical school as the sister university has become under the care of Professor Humphry and Dr. Michael Foster.

DEATH DUE TO MERCURIAL INUNCTIONS.—Two cases of dysentery with fatal results have been reported by a German physician. It appears that in both instances the blue ointment was used to excess. In one case over a drachm a day was rubbed in, and in the second, four and a half drachms a day were consumed.

A NEW MEDICAL COLLEGE IN BROOKLYN.—Brooklyn, N. Y., has a new institution, called "The College of Physicians and Surgeons of St. Mary's Hospital of the City of Brooklyn."

PROTESTING AGAINST THE PROPOSED "DICTIONARY OF MEDICAL SPECIALISTS."—The *Hospital Gazette*, in its issue of September 8, 1888, is pleased to see that the *Lancet* has also protested against the publication of the specialist dictionary. It justly points out that such a compilation cannot evidently be intended for the use of medical men, since everyone knows well enough beforehand to whom he should send cases requiring special treatment. All it can do is to enable the public to go a step further in repudiating the assistance and advice of the general practitioner before consulting the specialist. In other words, it is merely a barefaced attempt to advertise a class of men who, in many instances, never miss an opportunity for self-advertisement as it is. The specialist is, or should be, essentially the assistant of the practitioner, and not his *remplaçant.*

DAMAGES FOR SYPHILITIC INFECTION.—By a recent decision of a Paris court the parents of a child suffering from hereditary syphilis, which communicated the disease to its nurse, were condemned to pay $400 damages to the woman. Each of them had also to pay a fine of $20. The decision was grounded on the clauses of the Code providing for the punishment for wounds or other injuries inflicted through carelessness. The parents were aware of their child's condition.

ABANDONMENT OF INTUBATION AT LEIPZIG.—Professor Thiersch has given intubation in diptheritic laryngitis a thorough trial, extending over a period of some months, but with no results, so that he has now resumed his former treatment—tracheotomy, with which his percentage of recoveries is about fifty. He ascribes his lack of success, as compared with American surgeons in the matter of intubation, to a different type of the disease, thinking that in his cases the membrane is thicker and tougher and the constitutional symptoms severer.—*Correspondent Western Medical Reporter.*

INSUFFICIENT VACCINATION IN PARIS.—Out of the five thousand children born every month in Paris, only a thousand are vaccinated by the medical officers appointed for that purpose (*The Medical Press*). The remaining four thousand infants are therefore either vaccinated by private practitioners or not at all. Seeing, however, that more than half the population apply for and receive gratuitous medical attendance, and that half the burials are gratuitous, it is very unlikely that all the four thousand are vaccinated at the cost of the parents. It may fairly be assumed that a large proportion are not vaccinated at all, and that is why small-pox exists as an endemic disease at Paris, and does not disappear, as it has done, to a great extent, in Germany.

A HIGH TARIFF FOR CORPSES.—The transportation of bodies for purposes of burial or cremation is never a very cheap undertaking; but now it appears that custom duties are to be levied on dead bodies to such an extent that it may be cheaper to live than to die. The Italian authorities have recently exacted $75 as an import duty for a body crossing their frontier, and a second $75 was charged for carrying the ashes back again, after cremation of the body. This looks like extreme protection for home corpses.

UNSAVORY PEPTONES.—It is stated on good authority that the excrements of dogs are now collected in Paris, and worked up into "peptones" and powdered "extracts of meat." Paris still leads the world in some things.

A GERMAN Society of Dermatology has just been founded. All German-speaking doctors will be eligible for membership. The meetings of the Society are to take place during the Whitsuntide vacation every year in a town in Germany or Austria. The provisional committee consists of Professors Caspary, of Königsberg; Doutrelepont, of Bonn; Kaposi, of Vienna; Lewin, of Berlin; Lipp, of Gratz; Neisser, of Breslau; Neumann, of Vienna; and Pick, of Prague. The dues have been fixed at 10 marks (which is equivalent to $2.50 of our money) per annum.

A GARBAGE CREMATORY FOR PHILADELPHIA is said to be contemplated. New York should follow the lead of cities like Chicago, Montreal, and others, and erect one or more of these life-saving buildings.

PROFESSOR HOFMEIR has received and accepted a call to the Chair of Gynecology and Obstetrics at the University of Würzburg. He is only thirty-three years of age, but he is the son-in-law of the late Carl Schröder.

A MEDICAL DRAMATIST.—A play from the pen of Dr. G. H. R. Dabbs, of Shanklin, England, will be produced under the auspices of Mr. H. J. Leslie at a special *matinée* at the Prince of Wales' Theatre early in October. The title of the piece, which is said to deal somewhat largely with medical matters, is "Blackmail," which would appear to justify the assumption that the play is rather sensational.

A FOREIGN ESTIMATE OF INTUBATION.—The Swiss correspondent of the *British Medical Journal* writes as follows: "At a meeting of the Société Vaudoise de Médecine, Dr. Irwin H. Hance, of the New York Hospital for Children, made a communication on O'Dwyer's intubation of the larynx, based on eight hundred and six American cases, with 27.4 per cent. recoveries. Referring to Hance's paper, Dr. E. Thomas, of Geneva, says that he has assisted in eleven cases of intubation performed by Dr. D'Heilly in the Hôpital Trousseau in Paris. Only two of the eleven recovered. On the whole, as the matter stands at present, Dr. Thomas believes that the procedure has only two distinct advantages, namely—1, it is bloodless, and hence readily consented to by parents; and, 2, it allows the child to breathe air previously warmed in the oral cavity as under normal conditions. In its present imperfect form, however, O'Dwyer's procedure is thought to have many inconveniences and difficulties, which will, for some time at least, prevent it from superseding tracheotomy. 'Undoubtedly,' Dr. Thomas says, 'the latter operation is far from easy, but it requires less complicated instruments. The practitioner's eye can guide his bistoury all the while. The operation can be performed just as rapidly as perhaps intubation, while the after-management is easier. In addition, the curative effects of the intubation remain yet to be determined.'"

A HAPPY LAND.—There is not in France a medical school which has a professor of gynecology, nor is there in the whole country a special hospital for the diseases of women.

DR. HARVEY JEWETT OF CANANDAIGUA, N. Y., died suddenly at his home on the night of September 4, 1888. He had been engaged in the active practice of medicine for fifty-six years, and passed away in his sleep from sudden heart-failure, after a day of unusual professional activity. Dr. Jewett was president of the Medical Society of this State in 1883. He was known to many of the profession by his advocacy of the more general use of apocynum cannabinum as a diuretic in dropsy, to which he directed attention in a paper read before the State Society in 1869.

THE STOLID CHINAMAN.—Making allowance for some exaggeration, there is probably an undercurrent of truth in what a writer in the *North China Herald*, of Shanghai, says as to the absence of "nerves" in the Chinese. "To the average Celestial it is a matter of indifference how long he remains in one position. He will write all day like an automaton, he will work from morn to eve without any variation, and apparently without any consciousness of the monotony. The Chinese school children will undergo an amount of confinement, unrelieved by recesses or changes of work, which would drive a western pupil to the verge of insanity. Even Chinese infants are said to remain as impassive as 'mud gods.' To the Chinese exercise appears to be superfluous, and they can sleep anywhere. With a brick for a pillow the 'heathen Chinee' can lie down on his bed of stalks, or mud bricks, or rattan, and sleep the sleep of the just, with no reference to the rest of creation. He does not want a darkened room, nor does he require others to be still. The 'infant crying in the night' may continue to cry for all he cares; it does not disturb him. In the case of most working people, and also in that of many others, position in sleep is of no sort of consequence. It would be easy to raise in China an army of a million men—nay, of ten millions—tested by competitive examination as to their capacity to go to sleep across three wheelbarrows, head downward like a spider, their mouths wide open, and a fly inside."—*British Medical Journal.*

Pepsin as it Should Be.—As generally presented, pepsin consists of the real ferment incorporated with mucus and peptones, and unless prepared in a certain manner it will absorb moisture and putrefy. Such a specimen emits a nauseous odor, and has little or no digestive power. The best manufacturers have succeeded in securing a product which is non-hygroscopic, free from peptones, very soluble even in pure water, and capable of dissolving from 1,500 to 2,000 times its weight of coagulated egg albumen. Two grains of such a pepsin in twenty drops of dilute HCl and water is about as sure a remedy in certain forms of gastric derangement as we can ever hope to have. In order to disguise the odor and taste of the older preparations, it used to be the fashion to saccharate pepsins. With the perfected and purified products this is not essential. The failure of many to obtain good results from pepsin is due to the facts above mentioned. In order to demonstrate the worth of a given specimen, it is only necessary to go to a little very instructive trouble and perform the test as described in the U. S. P., or works on physiology. Where saccharated preparations are used, allowance must be made for the fifty per cent. of sugar which they contain. There is no excuse nowadays for any material variation in the activity of a given brand of pepsin. It should be assayed and brought up to the standard strength before leaving the manufactory, and that strength should be that of which a given and convenient bulk is capable of exerting a decided effect.—*Dr. Fowler*, *Dietetic Gazette.*

Obituary.

THOMAS T. SABINE, M. D.,

NEW YORK.

But few of the noted medical men who have passed away within the past year have been more universally regretted than Professor Thomas T. Sabine of this city. Although an invalid for nearly the whole period of his professional life, he proved how much faithful and arduous work could be accomplished under trying circumstances of physical disability. No one can appreciate such a trial more thoroughly than the medical man himself, who is convinced that his disease is incurable and that he must stubbornly work his way without hope. There is no heroism superior to this. Dr. Sabine bravely faced such an issue, and kept busily engaged in his beloved pursuit until the inevitable came and the galling harness dropped with him. Born and educated in this city, he graduated from the College of Physicians and Surgeons in 1864, after which he served in the house staff of the New York Hospital. At the completion of his term in that institution he was attacked with pulmonary hemorrhage, which laid the foundation of his life-long invalidism. With a power of endurance and indomitableness of will strangely at variance with his slender frame and bodily weakness, he accepted and filled the onerous positions of hospital surgeon at Bellevue and St. Luke's Hospitals, and also the chair of anatomy in the College of Physicians and Surgeons. As an operator he was conscientious, bold, and brilliant, and as a teacher he was impressive and thorough, and had the rare faculty of making the study of his subject a pleasure as well as a profit. Socially he was much beloved by his friends, uniting, as he did, a Christian resignation with a love for truth, honor, and fairness in all things, which rounded out a truly lovable character.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, September 24, 1888.

Laurence Johnson, M.D., President, in the Chair.

NOMINATIONS FOR OFFICE.

For *President*, Dr. Laurence Johnson (declined), Dr. Alexander S. Hunter; for *Vice-President*, Dr. L. Bolton Bangs, present incumbent; for *Secretary*, Dr. C. H. Avery, present incumbent; for *Assistant Secretary*, Dr. William E. Bullard, Dr. Charles E. Bruce; for *Treasurer*, Dr. J. S. Warren, Dr. H. E. Cramptom; for *Censors* (five to be elected), Drs. J. Leonard Corning, Laurence Johnson, M. N. Miller, William Stevens, Daniel Lewis, W. E. Bullard, Andrew F. Currier, and Robert Campbell.

John R. Bartlett, Esq., read a paper on

ADDITIONAL WATER-SUPPLY TO NEW YORK CITY, INDEPENDENT OF THE CROTON WATER-SHED.

There was much misunderstanding regarding New York's water-supply. The average annual rainfall in this latitude was a known quantity, stated to be about 43.08 inches, and the minimum to be about thirty inches. It was not safe to base estimates on more than the minimum rainfall, since not more than that amount could be relied upon under all conditions for supplying a large city with water. About sixty per cent of the annual fall on the Croton water-shed was lost by evaporation, absorption by vegetation, and percolation through the ground. This left forty per cent. of thirty inches, the minimum fall, which could be relied upon with safety. This amounted to a sheet of water twelve inches in depth, covering an area, on the Croton water-shed, of three hundred and sixty-one square miles. One square mile of water twelve inches in depth amounted to about two hundred and nine million gallons; this gave for the daily supply about two hundred and seven million gallons. If the average rainfall of forty-three inches were taken, it would give for the daily supply about two hundred and ninety-three million gallons. Two hundred and fifty million gallons a day would be ample for the needs of this city at present if we had it, but this amount could not be obtained for a number of years, not before six years after work should have been commenced on the Quaker Bridge dam and the reservoirs, and when these storage reservoirs should have been completed years hence, the population of the city would have been very greatly increased. It was now estimated to increase at the rate of about seventy thousand persons yearly. In other words, an ample supply of water from the Croton water-shed could never be obtained for the city of New York, and it was futile to wait for what never could come.

Mr. Bartlett then turned his attention to the Passaic water-shed, a small part of which lay in Rockland and Orange Counties, New York, the remainder in New Jersey. It was much nearer to the city than the Croton water-shed, had a much higher elevation, being from one thousand to one thousand five hundred feet above tide-water; its water came from forest-clad hills, the soil absorbed little of it in its downward flow, and it was very pure. The area was eight hundred and seven square miles, which gave for use about seven hundred million gallons a day. This quantity was amply sufficient to supply Newark, Jersey City, and other cities in New Jersey, and the lower portion of New York City. The company which he represented had secured the necessary riparian rights, and proposed to carry the water to a reservoir in the Orange Mountains, from which it could be distributed to the several cities through a system of pipes, with a force sufficient to raise the water to the tops of the highest buildings in the down-town portion of New York. If necessary, it could be conducted into this city under a head-pressure of three hundred feet. It would pass beneath the Hudson River in pipes laid in a tunnel, which could be completed within three years. The company asked the city to pay nothing until the water was delivered, and then the cost would probably be about the present rates. But the advantages would be far beyond the present system, since the water would come with sufficient pressure to be used in extinguishing fires, in manufacturing, and in quantity sufficient to flush the sewers and cleanse the streets. The need of an additional water-supply from a sanitary point of view, was made evident by the fact that the death-rate in New York City was greater than that of Bombay or Calcutta. A brief review of the water-supply of Rome and other cities was given, showing the importance the ancients attributed to a plentiful supply of pure water.

After a little discussion on the paper, DR. DAVID WEBSTER said he had had several conversations with Mr. Bartlett on his proposed method of supplying the city with water, and had become deeply interested in it, and hoped his project might be carried through; and he thought it would aid Mr. Bartlett in getting the consent of the city authorities, if the Society would adopt certain resolutions which he would offer, and he would be glad to see them adopted unanimously:

Whereas, The present scarcity of water in this city is causing great inconvenience as well as serious apprehensions for sanitary and other reasons; and,

Whereas, The new aqueduct will not materially increase the present supply of the Croton water-shed until the storage reservoirs shall be completed, six or more years from now; and,

Whereas, The upper portion of the city, with its rapidly growing population, will soon require all water that can be secured from that source; and,

Whereas, The present insufficient quantity of water endangers the safety of the city and promotes the spread of scarlet fever, diphtheria, and other diseases; therefore, be it

Resolved, That this society has listened to the explanation of the plans proposed by John R. Bartlett, Esq., for furnishing the city of New York with an additional supply of pure water, from a source independent of the Croton water-shed; that it approves the same, and urgently recommends it to the city authorities having the matter in charge.

DR. THOMAS H. MANLEY opposed the resolution, for, although he had not heard the entire paper read, he believed when the new aqueduct should be completed, the city would have an ample supply of water; such, at any rate, had been the opinion expressed by some very competent engineers. Moreover, it would be impracticable to deliver water into this city under the pressure proposed by Mr. Bartlett without a revolution of our plumbing system; the pipes would burst. He did not think it well to commit the Society to a plan of this kind. The meeting was not representative, in that it was not as full as it might be, had it been known that it was proposed to endorse this plan. He hoped the matter would be laid over.

DR. J. L. CORNING heartily endorsed the scheme. The company did not ask anything of the city until it should have complied with the contract and delivered the water.

DR. MORRIS thought the Society had nothing to do with the question of water-supply for suppressing conflagrations, but it should have something to say about the present insufficient amount of water, which was adding to the death-rate from disease. Fully seventy-five per cent. of the tenement-houses could not get water under pressure from 7 A.M. to 6 P.M. He was in favor of an increased supply of water. The question of getting water from Lake George would never be entertained by the city, because of the too-great cost.

A member asked whether the Society was aware that some years ago, a company offered to bring water from Lake George on the same terms that this company proposed to do, and it was rejected.

DR. E. C. HARDWOOD could see no objection to the resolutions, and thought the Society should be in favor of a measure which would add to the water-supply of the city. He would be in favor of pumping water from the Hudson with which to extinguish conflagrations and to flush the streets.

DR. COLE had the greatest regard for the author of the resolution, but he was diametrically opposed to it. It had been said that it meant little; that the Society did not endorse this particular scheme in adopting the resolution; that was nonsense. Should the resolution be adopted, it would mean that the particular scheme proposed was endorsed, and that the Medical Society of the County of New York favored a water-supply of the city by a private corporation. We expected within three years to have an increased water-supply of as pure water as any city had. He doubted whether the private corporation could carry out its plans as proposed. It had been thirteen years since the tunnel was started under the Hudson; this company proposed to build it within three years. Once a company proposed, as had already been stated, to bring water from the Adirondacks, from Lake George—perfectly pure, limpid water—buy its own right of way, and deliver it to the city in unlimited quantity on the same terms as Mr. Bartlett proposed, *i.e.*, to be allowed to charge the citizens the present rates. The gentlemen who read the paper represented a private corporation, and they wanted to make money. He objected to the resolution.

DR. TANSLEY and DR. TUTTLE spoke in favor of the resolution, and some of those who had favored its passage explained that they understood the resolution to mean only that those who voted for it favored an increased and ample water-supply for the city.

The resolution was adopted, with several dissenting voices.

The paper by DR. PAUL F. MUNDÉ, "The Value of the Operation of Shortening the Round Ligaments of the Uterus, Based on the Results of Twenty-one Cases," was read by title.

A proposed amendment to the by-laws, to be voted upon at the next meeting, is as follows: It shall be the duty of the comitia minora to provide for the annual publication of a Medical Directory of the City of New York.

Back volumes of the Transactions of the Medical Society of the State of New York can be obtained of the librarian of the Academy of Medicine, for twenty-five cents each.

"DYNAMIC" COMPOUNDS OF GOLD.—A specimen of the quasi-scientific methods of certain French therapeutists is given in the accounts recently published of a "discovery," by one Dr. Addison, of a mode of dynamically compounding arsenic and gold. This preparation we are told, as though it were something surprising, "possesses the valuable therapeutical properties of both substances. Gold, it is well known, is used in different preparations (gold iodide, auric acid, etc.), with excellent results, in the treatment of diseases of the skin, syphilis, amenorrhœa, etc. Arsenic is successfully employed in hysteria, scrofula, rheumatism, irritable forms of tuberculosis, and in other affections. Its action is strengthening and antiphlogistic. It moderates fever, and acts as a sedative. Dr. Addison's dynamic arseniate of gold, which is destined to render great services in the treatment of cutaneous affections, secondary and tertiary syphilis, different forms of cachexia, nervous diseases, etc., is employed in progressive doses, from one to thirty milligrammes. It is highly digestible." There is probably not a sound clinical observation showing that gold possesses any special therapeutic efficacy in any disease.

AMERICAN RHINOLOGICAL ASSOCIATION.

Sixth Annual Meeting, held at Cincinnati, O., September 12, 13, *and* 14, 1888.

WEDNESDAY SEPTEMBER 12TH—FIRST DAY—MORNING SESSION.

THE Association met at the Gibson House, and was called to order by the President, Dr. C. H. von Klein, of Dayton, O., at 10.15 A.M.

DR. A. B. THRASHER, of Cincinnati, Chairman of the Committee of Arrangements, delivered a neat, timely, and extemporaneous address of welcome, in which he expressed very great pleasure in giving the members of the Association a hearty welcome on behalf of not only the Committee of Arrangements, but of the entire medical profession of the central city.

PRESIDENT VON KLEIN delivered his address, which was devoted principally to the progress of rhinology and the distinction it had attained as a specialty during the past few years. An academic training was indispensably requisite to a medical education. Broad culture produced exalted ideas and inflamed the student to become a hero in the conquest of nature.

DR. J. E. SCHADLE, of St. Paul, read a paper on

CHOREA OF THE SOFT PALATE,

caused by the hypertrophy and hyperæsthesia of the mucous membrane covering both inferior turbinated bodies.

That the origin of not a few reflex nervous disorders can with a certain degree of exactness be traced to the presence of morbid conditions of the naso-pharyngeal cavities, is a question no longer doubted. Some forms of headache and of spasmodic asthma are in many instances the outgrowth of a nasal polypus, a turbinated thickening, or a septal deformity. These reflex neurotic disturbances disappear soon after appropriate measures of treatment have been directed toward the removal of their cause.

CASE I.—The patient first came under the observation Dr. Baker, of St. Paul. The only thing complained of was a constant contraction and relaxation of the levatores palati. Each contraction carried the uvula upward and backward till it came in contact momentarily with the upper and back part of the pharynx. The relaxation and separation of the moist mucous membrane surfaces caused the sound. The noise was like that produced by a rapidly ticking watch, and of the same frequency. The young lady was in excellent health, all the bodily functions being well performed. Dr. Baker's treatment was: ℞., Zinci bromidi, ʒ j.; syr. simplicis, f ℥ j. M. Sig.—Ten drops in water four times a day, increase one drop each day until the dose nauseates.

This not producing the desired result, he gave tr. physostigmatis in doses ranging from fifteen to thirty drops. After continuing this for a time, he abandoned it and prescribed fluid extract of cimicif. rac., in doses of f. ʒ ss. to f. ʒ j. every four hours.

July 7, 1887, galvanism was begun. Eight cells of the McIntosh battery were used, the positive pole with a sponge electrode being placed at the back of the neck; the negative pole with a metal-tipped electrode was applied to the palate, just above the uvula. The sittings were of five to ten minutes' duration, and the number of cells increased to eleven. Examination showed enlarged tonsils, with evidence of throat and nose disease.

The patient was examined by Dr. Schadle on the 16th of April, 1888. She suffered from constipation and flatulency quite frequently. The heart's action is more or less excited; the heart beats tumultuously when ascending a flight of stairs, a hill, or some other elevation. She complains in a marked degree of obstructed nose breathing. Voice is impaired, especially when attempting to produce head-tones, as in singing. The principal affection complained of, and for which she was referred to him, was the spasmodic movement of the velum palati.

A faucial examination reveals distinct rhythmical choreiform movements of the velum palati, accompanied by a peculiar clicking sound, distinctly audible for a distance of twelve or fifteen feet from the patient. Anterior rhinoscopic examination reveals chronic hypertrophy of the inferior turbinated bones, and, in a more marked degree, of the middle one, the presence of whose redundant tissue exerts pressure on the septum and produces obstruction of the middle meatus.

The treatment was mainly surgical. The first impression entertained was that possibly the enlarged pharyngeal tonsil might have been a source of the trouble, and that a thorough removal of it would do away with a foreign element constantly coming in contact with the opposing surface of the velum palati, and exciting thus into action clonic spasms. Snaring was impracticable. By the use of Cohen's post-nasal cutting forceps and the electro-cautery he reduced the growth in its entirety, a procedure which was followed by cessation of the choreiform movements, which remained absent for a period of two weeks, when they suddenly returned during a spell of nervous excitement from which the young lady was suffering. Attention was next directed to treatment of the nasal passages. The pathological changes found in them offered a theory for a reflex cause of the affection. Cocainizing the intranasal mucous membrane generally produced relief for half an hour. With a view to reducing the hyperæsthesia and hypertrophy of the turbinated bodies, he employed the electro-cautery, thoroughly burning the affected parts. The trouble at once ceased. Nose-breathing displaced mouth-breathing, and the dry sensation and sticky secretions of the pharynx gradually disappeared. The functional disturbances of the heart and shortness of breath passed off, while the general nervous system gained tone. Patient can now speak and sing with a clearer voice; the head-tones are improving daily. Beyond a doubt a cure has been produced, the permanency of which has already been severely tested.

DR. JOHN NORTH, of Keokuk, in opening the discussion, said he was very much pleased with Dr. Schadle's paper, and more particularly with the results obtained by his treatment. The case had been in the hands of excellent physicians previously, who had overlooked the nasal trouble, and it was especially interesting to rhinologists to learn that the cause of the trouble was found to be in the nose, and that by applying treatment to the nasal passages relief was obtained.

DR. J. G. CARPENTER, of Standford, Ky., was convinced that the subject of rhinology was ignored more or less by general practitioners. When a patient presents himself to him with a bronchitis, laryngitis, or asthma, he invariably examines the naso-pharyngeal chambers, and usually finds the starting-point there in many affections, and by treating the nasal chambers other troubles subside.

DR. A. G. HOBBS, of Atlanta, regarded the paper as an exceedingly interesting one. He had never encountered such a case in his practice, nor seen a description of one that at all approximated it.

A paper on "A Short Criticism on the Prevalent Methods of Treating Diseases of the Upper Air-passages," by Dr. R. W. Wilcox, of New York City, was read by title.

AFTERNOON SESSION.

DR. T. F. RUMBOLD, of St. Louis, Mo., read a paper on

THE ETIOLOGY AND PATHOLOGY OF NASAL DISEASES.

The etiology of a disease is of the greatest import. A perfect understanding of its causes and its mechanism is the goal of the pathologist. To be able to define, with some degree of clearness, the various changes that take place, from the first cold in the infant, through the various stages of chronic rhinitis, not merely giving the symptoms or a cursory description of its morbid anatomy, but by studying its causes and the course that the injurious impressions take to reach the ultimate region where we see the manifestations of abnormal action, is to do much toward directing its hygienic and therapeutic management.

Speaking of hereditary predispositions, he would ask the question: "Does heredity have anything to do in causing rhinitis?" The negation to this question is given in the description of a primary cell and the mechanism of rhinal inflammation. He had long been convinced that heredity, as a cause of disease, is an erroneous theory. It is a daily occurrence for a patient to express fear concerning the condition of his lungs, because of having a relative who died of lung trouble, fearing that the disease may have been inherited. About the first thing many physicians ask such an individual is: "Have you had a relative die of consumption?" On receiving an affirmative answer, a significant nod of the physician's head is all that is wanted to make the poor frightened fellow think of death. All that is required to shorten the life of a person thus afflicted is to thoroughly frighten him and then maintain his mind in this condition; his appetite and sleep will soon be seriously disturbed, which will surely diminish his weight and strength.

The histological facts concerning cell-life will prove a successful contravention to the theory of heredity. We know life only in combination with organized substance. A living cell is composed of finely granular matter, and has a pale, slimy appearance that is called protoplasm. The cell usually contains a structure resembling a vesicle, called a nucleus; the form of this may be round, oval, or irregular. In the interior of the nucleus are small bodies called nucleus corpuscles; it also contains nucleus substance and nucleus juice. In its natural stage it develops on its surface a distinct membrane. The cell, according to Virchow, has a threefold vital activity. He distinguishes one of these as *nutritive*, that is, displaying activity toward its own preservation; another as *formative*, or showing an activity in its own propagation; and, lastly, as *functional*, that is, its behavior in its outward relation to other parts. During the life of a normal cell, under normal circumstances, it displays no other kind of activity. Its component parts render it incapable of any other kind of activity, consequently there are no changes, except the physiological changes; nor can any combination of these three activities result in disease. If the cell maintains its normal surroundings, it will live out its physiological life and disappear according to the laws of its own existence. Nothing can change these activities, except what comes from without. The nature of the surroundings influences every cell, whether singly or joined with others. These surroundings may be favorable or unfavorable to one or all of these activities. But the influence of heredity must come from within, if it comes at all. But the law of the cell's life contradicts this, and there is no avoiding this law; no cell can be influenced, except from without; all inside influences are normal influences. To some extent the cell is uninfluenced by its surroundings by virtue of its own inherent vital force; but this range of independence is very limited. If the external conditions of the cell deviate from the normal, then disturbances of cell-activity show themselves at once. The deviations from the normal action may be but slight, or may end in death.

"The Influence of Morbid States or Conditions of the Body on Local Diseases" was the title of a paper by Dr. H. Christopher, of St. Joseph, Mo.

There are several disposing causes and conditions of a constitutional character which are intimately connected with local diseases, and which are to be considered in their treatment. The principal of these are:

1. Diatheses or constitutional tendencies, with local manifestations or points of eruption (malignant).
2. Constitutional tendencies, attended or not by local morbid action of a non-malignant character, as the strumous habit or rheumatic diathesis.
3. Constitutional disturbance affecting the functions of certain organs, which in turn give rise to morbid action in others.
4. Abnormal action or deranged function of certain organs, giving rise to morbid action in other organs uniformly or contingently, as in metastases or functional action of the heart from functional derangement of the digestive organs.
5. Purely local morbid action, as in local inflammations and non malignant tumors, and some diseases of the skin.

All these states of the body, excepting the first and last, are not infrequently found to exist with local inflammation of the nasal, pharyngeal, and aural cavities, and to influence and determine in no small degree their management.

Dr. John North read a paper on

THE RELATION OF NASAL DISEASES TO OTHER DISEASES, INCLUDING THE BRAIN AND NERVOUS SYSTEM.

He began by saying that there is no organ in the entire body that has been so neglected as that of the nose. Obscure and obstinate diseases have not yielded to treatment because it has been directed to the effect of nasal reflex troubles, and not to the nose, the cause of the trouble.

In 1886 he attempted to show that neurasthenia was frequently the result of chronic naso-pharyngeal catarrh, and in support of the theory he reported several cases of neurasthenia that yielded to treatment applied to the naso-pharynx.

In a paper read before the Association at Washington, 1887, he claimed that catarrh, or rhinitis, as it is usually called, was not an inflammation, but a condition produced by a paresis of the ganglia of the sympathetic nervous system supplying the parts. Without doubt asthma is caused by vaso-motor paresis causing a dilatation of the vessels. It is a well-known fact that disease in one part or organ will cause, through the agency of the sympathetic nervous system, derangement in another organ, even in remote portions of the body.

Drs. McKenzie, of Baltimore; Daly, of Pittsburg; Rae, of Rochester; Seiler, of Philadelpnia; Schadle, of St. Paul; Bosworth, of New York, and others in this country, besides a number of European rhino-laryngologists, have reported cases of asthma and hay fever dependent upon the diseased condition of the nasal cavities.

Dr. Thomas F. Rumbold read a paper on

THE EFFECT OF NASAL INFLAMMATION ON THE MIND.

The normal condition of the mind depends upon a normal supply of blood to the normal brain. An abnormal supply of blood, even to the healthy brain, will produce an abnormal condition of the mental faculties. Dr. Rumbold had noticed for many years that in every patient who had suffered an attack of cold in the nasal passages, olfaction was almost completely obtunded, with the mental powers more or less lowered in their capacity. It follows that if an acute inflammation in the nasal passages is accompanied by mental manifestations, that mental incapacity of a more severe character must accompany a chronic rhinitis. Clinical observation has shown that this is the case.

Dr. J. G. Carpenter, of Standford, Ky., read a paper on

THE ETIOLOGY AND PATHOLOGY OF ACUTE CATARRH.

Among the most prominent causes he mentioned occupations attended with much dust, smoke, excessive moisture, or dry, dusty atmosphere, going about insufficiently clad, the evil results of the ordinary slippers, etc. Seal-skin sacques, while they were very beneficial in cold weather, are capable of doing great evil when worn imprudently. Pathologically, acute catarrh is divided into three stages: 1. The dry stage, attended with hyperæmia, redness, heat, tumefaction, and pain of mucous membrane, the latter presenting a red, dry, or dark-red appearance. 2. Moist stage, supplementing the first, there is transudation of serum, diapedesis of the white corpuscles into the connective tissue, cell-proliferation, and organization of lymph. The mucous follicles and glands are enlarged and distended, and excessively active. 3. The purulent stage, the presence of pathological conditions with denudation of the epithelium and presence of a raw surface, and the excessive mucous secretion is changed to a muco-purulent or purulent one.

THURSDAY, SEPTEMBER 13TH—SECOND DAY, MORNING SESSION.

The Association was called to order by the President at 10 o'clock.

DR. R. S. KNODE, of Fort Wayne, Ind., read a paper entitled

INTRANASAL OBSTRUCTIONS.

He said of all the mucous surfaces that of the nose is perhaps the most sensitive to irritating gases, vapors, and dusts of different kinds, as well as sudden changes of atmosphere, and it makes but little difference what the condition of the atmosphere may be to the one exposed, whether loaded with dust, an odor offensive or fragrant, hot or cold, pure or irritating, the nose must receive it, filter and purify it, warm and moisten it for the lungs.

Intranasal obstructions may be temporary or permanent, partial or complete, owing to the extent of inflammation or injury that produces them. Temporary occlusion is usually the result of some one of the forms of acute rhinitis. From whatever cause, with proper hygienic measures, the membrane usually regains its natural condition in the course of a few weeks. This, however, is not always the case. Occasionally from a very severe attack, or from the effects of repeated colds, we may find the membrane overwhelmed with plastic material; a loss of nerve-power, a pale, flabby, wrinkled condition somewhat resembling polypus, but more sensitive to the touch, and completely filling up both cavities of the nose. In this condition he had found nothing to act so promptly as to first use a one per cent. solution of cocaine, applied with a probe and cotton, and followed with mildly stimulating solutions of chromic acid, gr. 10 to ℥ j., after which the vaseline treatment should be used. If stenosis should return, a second application of the acid may be made, or slippery-elm plugs slightly moistened with a weak preparation of cocaine and listerine.

Dr. Knode's paper was followed by the report of a case of

ENLARGED TONSILS WITH PECULIAR SYMPTOMS RELIEVED BY THE GALVANO-CAUTERY SNARE,

by E. G. KEGLEY, of Cedar Rapids, Ia.

CASE.—Mr. B——, aged forty-three, consulted him in January, 1888, with regard to a trouble which he termed "druleing." The patient presented the appearance of one suffering from hay fever. His eyes were red and swollen, with excessive lachrymation, constant flowing and wiping of the nose, with the addition of a constant spitting of a clear fluid. On examination he found the nasal mucous membrane highly congested, and completely closing the nasal passages. The patient's mouth was constantly filled with saliva, and tonsils enormously enlarged, filling completely the back part of the mouth and throat. These spells were very common and lasted from one to two weeks. During the attacks he had no appetite; could not sleep because of a choking sensation and hot water in his mouth. He had consulted the best doctors in the country, but had derived no benefit from their treatment. Dr. Kegley watched the case through this attack, and told him to report himself when another made its appearance. In the meantime he saw him between the attacks and found the membranes of the nose normal, but the tonsils were very much hypertrophied. He therefore urged the patient to have the tonsils removed. He saw him again in about a month in another attack, but could do nothing for him. He then lost sight of him for a year, when patient returned and said he was ready to submit to anything. He was now suffering from a very severe attack. Dr. Kegley proceeded to cocainize the tonsils and removed them both at one sitting by means of the galvano-cautery snare, the patient declaring he experienced no pain to speak of. He saw the patient the next day, and he said the trouble had ceased almost simultaneously with the removal of the tonsils. He has had no further trouble.

AFTERNOON SESSION.

DR. A. G. HOBBS, of Atlanta, Ga., presented a paper on

THE SURGERY OF GUMMATOUS GROWTHS OF THE NASAL CAVITIES,

and reported four cases.

Case I. was brought to him to be treated for stenosis of the nasal passages. She was a young married woman, who had had syphilis for three years. The usual treatment was adopted, no syphilitic symptoms having shown themselves during the past year. An anterior examination revealed a purplish-red growth which filled the right nasal space completely, and pressed itself into the left cavity till the stenosis was almost, if not quite, complete. From the history of the case and the appearance of the growth its gummatous nature was suspected, hence it scarcely occurred to Dr. Hobbs at this time to attempt its removal by any surgical means for fear of producing a destructive ulceration. She was placed upon increased doses of iodine of potassium together with biniodide of mercury. This treatment was continued for four weeks without any marked benefit. Dr. Hobbs cocainized the nasal passages with a five per cent. spray as thoroughly as possible, then attempted to introduce a Blake's snare, but found it impossible to engage the tumor in the loop. A cutting spoon was introduced and several large masses of the growth cut away. The hemorrhage was very little. When the flow had ceased, she could breathe through the left nostril. Four more sittings, at intervals of three days, were necessary to remove the entire growth. The attachment was by a broad pedicle at the posterior part of the septum, which he seared with the galvano-cautery when the last particles of the growth that could be seen had been extracted. The patient was furnished with a spray apparatus; no ulceration followed. Six months afterward there had been no recurrence, and patient had regained her health completely. She was kept on antispecific treatment during the six months.

Case II. was one of hypertrophic nasal catarrh Jarvis' snare was used; operation same as in preceding case.

FRIDAY, SEPTEMBER 14TH—THIRD DAY, MORNING SESSION.

DR. A. B. THRASHER read a paper on

THE SURGICAL TREATMENT OF NASAL CATARRH.

He said there are forms of nasal catarrh that can only be benefited, and not cured, by medicinal treatment. When we have mechanical obstructions to the lumen of the nares of a hypertrophic, hyperplastic, or neoplastic character, surgery offers the most direct path to the removal of the difficulty. These are the cases of nasal catarrh which have passed from one doctor to another, have used all the advertised remedies, so called, and have at last concluded that nasal catarrh is incurable, and it is of no use to treat it.

Since the cavity of the nose is open to inspection, directly and indirectly, it is rather curious that surgeons have been so slow to invade this region. They will cut with impunity into the abdominal cavity and remove or examine the contained viscera; or open the thorax and tie an artery or evacuate an abscess; or even cut into the brain-box to elevate a depressed bone or remove a tumor, and yet stand with folded hands and do nothing to check the symptoms caused by a neoplasm springing from the middle turbinate, or a hypertrophy at the pharyngeal vault. This is not so curious when physicians stop to think that the removal of a growth from the posterior middle turbinated body requires more manual dexterity and tactile skill than to open the abdomen, thorax, or even the cranium itself.

When a simple enlargement of the turbinated body is encountered, which it is desirable to reduce or remove, what is the best method of procedure? There are cases in which the application of a chemical caustic answers the purpose admirably well. The Woakes' gouge or plough will do the work, and by the aid of cocaine will do it rapidly and painlessly.

In uncomplicated cases of chronic hypertrophic rhinitis the conditions to be met are: (*a*) Obstructions to lumen of nares, and (*b*) abnormal condition of mucous glands. The causal indications would at once suggest a removal of the redundant tissue. The means employed should look to the accomplishment of this end with the least resulting scar surface, so that the natural condition of the epithelial covering might be as nearly as possible simulated. To reach this result he had met with the most marked success in the use of the galvano-cautery knife. He first anæsthetizes the part with cocaine, then introduces the knife to the posterior part of the hypertrophy, turns the sharp edge toward the tissue to be cut, heats the knife white hot, and cuts deeply, drawing the knife forward. The result is a deep linear scar in an antero-posterior direction through the hypertrophic tissue. He cuts deeply enough to destroy a portion of the submucous erectile tissue. When this cut heals the result is a narrow linear scar, and by the natural contraction of the cicatricial tissue the surface becomes in time practically obliterated.

OFFICERS FOR 1889.—*President*—Dr. John North, Keokuk, Ia.; *First Vice-President*—Dr. A. G. Hobbs, Atlanta, Ga.; *Second Vice-President*—Dr. A. B. Thrasher, Cincinnati, O.; *Secretary* and *Treasurer*—Dr. R. S. Knode, Fort Wayne, Ind.; *Librarian*—Dr. N. R. Gordon, Springfield, Ill.; *Members of Council*—Hiram Christopher, M.D., St. Joseph, Mo.; J. G. Carpenter, M.D., Standford, Ky.; Thomas F. Rumbold, M.D., St. Louis, Mo., and J. G. Sinclair, M.D., Cincinnati, O.

Next place of meeting, Chicago, Ill.

PULMONARY ARTERY WITH TWO VALVES.—At a meeting of the Royal Academy of Medicine in Ireland, Dr. A. W. Foot exhibited a specimen of a pulmonary artery with two valves of equal size, and presenting no abnormal appearance other than unusual size. The heart exhibited was taken from a man, aged sixty-nine, who had long been subject to aortic regurgitation. Alluding to the rarity of this defect in the pulmonary valves, Dr. Foot observed that the only other example he knew of in Dublin had been found by Dr. Graves in a man, aged sixty-six, who died of pneumonia and pericarditis. In five museums in London Dr. Peacock had been able to obtain only nine specimens of two-valved pulmonary artery. Numerical irregularities in the semilunar valves were much more often observed in the aorta than in the pulmonary artery. Dr. Bewley said he once saw a similar form of aortic valve. It was taken from a man who had suffered from a nervous affection of the heart. There were two large flaps, each a good deal larger than the aortic flap, and between these a very small third flap, measuring between a third and a fifth of an inch across. They were all perfectly healthy. During life the aortic sounds of the heart had been perfectly healthy. Dr. Foot, in reply, said the formation of two ordinary-sized flaps, with a small one between them, was a well-known one. In the museum there was a pulmonary artery with four valves.—*British Medical Journal*, June 16, 1888.

BRITISH MEDICAL ASSOCIATION.

(Special Report for THE MEDICAL RECORD.)

Fifty-sixth Annual Meeting, held at Glasgow, Scotland, August 7, 8, 9, *and* 10, 1888.

(Continued from page 304.)

SECTION OF DISEASES OF CHILDREN.

WEDNESDAY, AUGUST 8TH—SECOND DAY.

DR. CHEADLE, the President, introduced a

DISCUSSION UPON RICKETS,

its etiology and prevention, its connection with syphilis and scurvy. Rickets, he said, was a general disease, and every one agreed that it was caused by bad nutrition. Congenital syphilis also had been assigned as a cause, and lack of fresh air, etc. It was not right to say that rickets was a phase of hereditary syphilis. Nor was it at all tenable to say that the disease was hereditary, for rickety children might be the offspring of perfectly healthy parents. Bad food, bad ventilation, and want of light certainly favored the disease, but these were not the only factors, for some children brought up in great squalor and ill fed did not become rickety, and some children of the comfortable classes were so. The quality of the food was apparently of more consequence than the quantity, and it was known that hand-fed children were very prone to the disease. Women who became pregnant while suckling were apt to cause rickets in the infant. Defective food, then, was the main cause of rickets, and it was especially seen in children fed on farinaceous food. It was not the presence of the starch, but the absence of other ingredients that did the mischief. Diet which was wanting in animal fat was peculiarly apt to produce rickets, and so was food devoid of nitrogenous elements. The abundance of fat in milk pointed to that fluid as an admirable preventive and cure of rickets. When children got plenty of this they soon were cured of their rickets. The young lions in the Zoological Gardens, London, used to be so rickety that they could not be reared. Now they were fed on flesh and milk, and got cod-liver oil, and for the first time in the history of British-reared lions they were in good health at the age of fifteen months. In addition there was probably a paucity of phosphate of lime in the diet of rickety children. As to the question put, whether enlargement of the liver and spleen was always present in rickets, he thought that this was only when rickets was combined with hereditary syphilis. The treatment of rickets should be rather dietetic than medicinal. Cream, or milk containing cream, was far more useful than cod-liver oil, although that was of benefit. Raw meat was of more service than iron.

PROFESSOR RANKE, of Munich, agreed with these views. There was no clear connection between scurvy and rickets, and as to syphilis, the great majority of the rickety children in Munich were not syphilitic.

DR. JACOBI, of New York, said that there was a certain degree of hereditary possibility from all kinds of constitutional disease. Digestive diseases of children were all apt to lead to rickets. Cow's milk, he thought, was often contra-indicated, for it differed greatly from that of women. He advocated the use of phosphorus in rickets, but it must not be given in salts of phosphorus. As to cod-liver oil, that could not be taken in America in summer. Twenty years ago rickets was rare in the United States; but since the great immigration of Irish, Germans, and Poles, it had begun to be common.

DR. CARMICHAEL, of Edinburgh, said that rickets was far from being very uncommon among the children of the well-to-do. In adipose rickety children the fat appearance marked the rickets to the popular eye. Now if children of the rich became rickety, a faulty diet must be the cause of it. Deficiency of fat in the diet was one great cause of the disease. In Edinburgh many of the children of the poor were brought up on the bottle, with Swiss milk or diluted cow's milk, and in both of these there was too little fat. He much approved of cod-liver oil by the mouth and in inunction.

Dr. Ashby, of Manchester, thought hereditary tendencies had a great place in the causation of rickets.

Dr. E. Owen, of London, thought that the worst cases of rickets were in children brought up on tinned foods. Rubbing in cod-liver oil was useful. Such children should be kept very clean. A great many cases of rachitic deformities in which the saw and chisel were used might be treated by far gentler means.

Dr. James Finlayson, of Glasgow, said it occurred to him that some points in

THE HISTORY OF RICKETS IN GLASGOW

were worth notice. The disease was formerly very uncommon in Glasgow, but now the reverse was the case. Glasgow was to be pre-eminent for rickets. Why was this? About thirty years ago there was a great accession of women operatives in the factories, and concomitantly with this an immense growth of the population. Children consequently were now ill fed, and it had been very difficult for children to get much milk of late years. Buttermilk was especially difficult to get, since it no longer was milk churned, but drunk in the form of new milk. Hence oatmeal and buttermilk, which were formerly much consumed by the poor, were no longer accessible to these children as before. Then, again, there was terrible overcrowding in Glasgow, and the children of the poor never saw the green fields as they used to do. This was the cause of the increase of rickets far more than the absurd cause alleged by some, *i.e.*, the introduction of Loch Katrine water, which was said to have too little lime in it.

SECTION OF PUBLIC MEDICINE.

Wednesday, August 8th—Second Day.

A DISCUSSION ON THE DISPOSAL OF SEWAGE AND ON SEWAGE FARMS

was opened by a paper from **Dr. Dyke**, of Merthyr-Tydvil, on the sewage disposal at Merthyr, South Wales. That gentleman narrated that in 1860 experiments were first made at Merthyr on the purification of the sewage, and Mr. Bailey Denton wasc alled in to consult on the best method. He advised that the sewage should be treated by downward intermittent filtration, and accordingly some land was prepared for this purpose. It was found that the workmen employed in no way suffered in health during the preparation of the sewage farm. Hence for seventeen years twenty acres were used for the filtration of the sewage of Merthyr—three hundred thousand gallons daily. This scheme was found to work so well that wide irrigation was then had recourse to, and forty acres of land were employed for a time. Lastly, two hundred and sixty-two acres were utilized by the Local Board, most of this being ordinary grass lands. The sewage was strained and then passed over the land, when potatoes, marigolds, and grass—twenty-six tons per acre—were the crops raised. The surface of the land became dry in a few hours. A rate of 4*d.* in the pound at first was needed, but latterly a profit of £983 per annum had been obtained. The population served by the farm was about one hundred thousand inhabitants. About one gallon of sewage per square yard was daily purified, and in the filtration beds the depth of soil was six feet, and three feet in the other or broad filtration. The question had been put whether such a plan was generally feasible for cities. The author of the paper replied in the affirmative.

Dr. Murray, of Forfar, mentioned that Forfar had always had considerable difficulty in its sewage disposal. To the west of the town lay the loch, a mile long, and for one thousand years the sewage of that town had drained into that piece of water, which was very deep. The town sloped downward to the loch. The soil was a light loam, and there was a natural drainage system. Latterly a nobleman, who came to reside in the neighborhood, objected to the pollution of the lake, and Mr. Bateman's advice was sought to know what to do with the sewage. He advised the town to filter the sewage through forty acres of soil by downward filtration. This was carried out: the sewage was lifted fifty feet and a good filter area secured. Grass, cabbage, carrots, and potatoes were raised, and it was found that the water did not freeze in winter, as it was warmer than the atmosphere. The general health of the persons living at the farm was excellent, and there was no effluvia noticed.

Dr. Carpenter, of Croydon, said that at the Leamington Congress in 1865 he had called attention to

THE SIMPLEST METHOD OF TREATING THE SEWAGE OF GREAT CITIES.

The best of all processes was that entitled broad irrigation. At the International Congress in London in 1881 he submitted some general propositions, which were, briefly, that the application of the sewage of a town with water-closets to the land is not injurious to the inhabitants if only the sewage were fresh, applied intermittently, and the effluent rapidly removed from the fields. The judicious application of sewage to suitable soils cleans the effluent and fits it for discharge into any ordinary stream, provided not more than two hundred and fifty persons be calculated to the acre. Vegetables grown on such sewage farms are quite wholesome, and no parasites are found in the animals fed with the grass of these farms. The cause of this was because the pathological germs were destroyed by the germs in the soil. Sewage farms might be carried on with perfect safety close to farms. It was a wise policy for a nation to encourage such farms in order to raise supplies of meat and milk. To be financially successful the rainfall should be separated from the sewage, and the crops employed to rear stock on the farm. It was well to have the sewage farm as near as possible to the city to be served; but if the water was running it might flow for twelve hours, even in summer, without losing its freshness. The utilization of the sewage on land near Croydon had been now carried out on the same land for nearly thirty years, commencing with thirty-six acres in 1851. It was found that this was too little, and three hundred acres were secured. The subsoil of the irrigated district is almost unaffected three feet below the surface, for the crops take away the manured part, and thus the soil can purify as well as ever, if only the cropping were incessant, the land being allowed to rest every now and then. The sewage should pass over the land rather than through it, and a sewage farm bears deep ploughing better than any other, and grows larger crops. The land at Beddington cost about £300 per acre, or £250,000 altogether, and yet the rate had been only 2*d.* in the pound. The capital was being paid off, and in forty years from the last loan Croydon would stand rent free on the farm; how unlike London; with its useless sewage-tanks at Barking and Crossness. The only mistake was when the Norwood farm was overtaxed with an excess of sewage. Dr. Angus Smith's report to the Local Government Board in 1879 was to the effect that this way of treating sewage was in every respect the best. As to the question of parasites, this had been thoroughly disproved, and the late Dr. Cobbold had at once withdrawn his opposition when he looked into the evidence. Croydon now utilized seven hundred acres for its sewage farms, and the only mistake was that the corporation did not keep enough stock on their farms, and hence they depreciated the value of their grass and other produce.

Dr. C. R. Drysdale read a paper on

THE BERLIN AND PARIS SEWAGE FARMS.

He said that the only rational and satisfactory way of treating the sewage of cities was by agricultural utilization of the sewage in suitable areas of fit soils, as was done in Berlin and Paris. The chief requisites of sewage irrigation are that the sewage shall quickly reach the fields in a fresh state, and that the soil shall be such that six hours after irrigation no one would know that it had taken place. Chalky and marshy soils are excellent for the purpose.

Dr. Whitelaw, of Kirkintilloch, read a paper on the sewage farm near that town, and several others presented communications on the same subject.

Dr. Christie read a paper on

CHOLERA AND ITS FOSTERING CONDITIONS IN THE ENDEMIC AREA,

written by Dr. W. J. Simpson, Medical Officer of Health, Calcutta. Dr. Simpson gave a full description of Calcutta, Howrah, and the suburbs, dwelling especially on the water-supply, the tanks, the drainage, the construction of the streets and houses, native and European; and the sanitary system generally. Calcutta, to the south of the native towns, he stated, is well built, the streets are wide and straight, the houses are large and have gardens attached; there is a liberal supply of excellent water, the drainage and cleansing are good, and that portion of the city compares favorably with the better parts of London. With a few exceptions, northern and native Calcutta is densely crowded, the streets are narrow and irregular, the drainage is bad, only the better and middle class have a fair supply of water; the poorer class have a very scanty water-supply, and depend upon the water in the tanks. The native town is studded with wells and tanks. Neither Howrah, with its 100,000 inhabitants, nor the suburbs of Calcutta, with their 250,000, have any public water-supply, with the exception of the wells and tanks. The insanitary condition of Howrah, without a public water-supply, and without building regulations, is surpassed by the suburbs, which have no public water-supply, no drainage, no building regulations, nor any effective conservancy arrangements. As a general rule, Europeans resident in Howrah get their water from Calcutta by carriers, and they avoid the well and tank water. The personal habits of the natives are cleanly. As a religious duty they bathe at least once a day, the women more frequently, and this is done, when convenient, in the river Hooghly, but generally in the tanks near their houses or huts. The tanks are thus defiled by the excretions of the body, by the washing of dirty clothes, frequently of clothes soiled by excretions of the sick, by human ordure due to the practice of children and others defecating on the banks of the tanks, and by the drainage and soakage from the surrounding huts and houses. Thus the water in the tanks, except during the rainy season, varies in quality from moderately polluted up to concentrated sewage, and this is the only water-supply practically available for large numbers of the native population.

Dr. Littlejohn introduced a discussion on

THE DISEASES COMMON TO MAN AND THE LOWER ANIMALS.

Dr. Littlejohn was sorry to say that he had just had a telegram from Professor Fleming, who was to have read the opening paper, regretting that sickness prevented his being present. He called therefore on Professor Waller, of Edinburgh, to inaugurate the discussion, and that gentleman said that anthrax was in front of all the diseases which came under discussion, but on this there was a certain amount of legislation already. Tuberculosis was a more debatable ground, and his opinion was that it should be included among the contagious diseases. It was one of the greatest pests both of man and beast. He himself had no doubt about the communicability of the disease from animals to man, and back again from man to animals, in every possible shape and form. It was undoubtedly communicable both by injection and inhalation. Of thirteen animals slaughtered in Edinburgh slaughter-houses, two or three months ago, on account of pleuro-pneumonia, six were affected with tuberculosis, so that his hearers might have an idea of the spread of the disease among dairy animals. Again, eighteen animals were slaughtered with the same result. Tuberculosis existed among poultry and ran a rapid course, and he believed it might be transmitted by eggs. Soon after he came to Edinburgh, in 1871, he lost a child, he believed, from drinking the milk of an animal which was tuberculous, and a member of the Privy Council had a similar record. It was not clearly proved that the disease arose from eating the flesh of such animals, but it was probable. Many dissection-wounds probably were bad from the injection of tubercle matter. He urged that a royal commission should be appointed to consider this question.

Dr. Farquharson, M.P., thought it was established that pearl disease and human tuberculosis were identical. There should be but little difficulty of detecting disease of the udder in cows. The question was a most alarming one. He recently, in the House of Commons, asked Mr. Ritchie whether he would not direct the Local Government Board to investigate this question. The reply was that they had no staff adequate to carry it on. Government wanted squeezing, and this should be done.

Professor Crookshank, of London, said that tuberculosis and actinomycosis were both possibly communicated from the cow. The idea had lately been broached by the medical department of the Local Government Board that scarlatina originated from the cow. He believed that if the facts which had come to light from the investigations of other inquirers had been known to Mr. Powers and Dr. Klein, these hypotheses of scarlet fever being of bovine origin would not have been started in the Hendon inquiry. A full report on this subject had been presented to both houses of Parliament, and would speedily come into the hands of the public.

Dr. Burst, of Edinburgh, spoke of the divergency of opinion as to the identity or non-identity of small-pox and cow-pox. If this was a difficult question, that of scarlet fever was more so.

Dr. Edington, of Edinburgh, thought that the evidence of the communication of scarlet fever from cattle was as yet unproved. Dr. Klein had, indeed, put forth a microbe as being the cause of scarlet fever, but he had not shown that this microbe was the origin of scarlet fever in the human race. With regard to his own investigations, he had spent a very long time on the investigation of this question, and had had as yet no one who had been good enough in this country to try to verify his conclusions. A gentleman in the United States had asked him for a slide containing the microbe which he considered to be the cause of human scarlet fever. This had been sent by Dr. Edington, and inoculation of guinea-pigs with it had, in one instance, produced a febrile condition with falling of the hair.

Dr. Tomkins, of Leicester, said that it was supposed by some persons that cases of malignant pustule (anthrax) in cattle were extremely rare in this country, but in this he thought they were mistaken. In 1883, there had been a case of malignant pustule in Leicester, where the patient had been infected by coming in contact with the flesh of some diseased cattle. The discussion, he thought, should have been rather more narrowed, and it would have been better to confine it to one subject, such as the communication of tuberculosis from animals to man. It was most remarkable what a large number of animals brought to the slaughter-houses in large cities suffered from pearl disease. No less than fifty per cent., in some cases, were found to contain pearl disease. There was a great deal of evidence that tuberculosis was derived from such animals, and it was certainly highly probable that this was the case. The same remark applied to scarlet fever. He held that it would be most important that the Local Government Board should issue a committee to investigate the possible communicability of tuberculosis from the meat and milk of such diseased animals; and he was indeed sorry to hear from Dr. Farquharson that the Local Government Board had no funds at its disposal for such an inquiry. For although, doubtless, there were many willing and able private experimenters in all of our cities, yet the inquiry was an expensive one and required larger funds than they could command.

Mr. William Brown, of Carlisle, read a paper on an outbreak of

TYPHOID FEVER ASSOCIATED WITH AN INFECTIVE FEVER IN COWS,

which he had witnessed in the neighborhood of Carlisle.

Dr. Heine, of Bradford, was then called upon by the president of the section, and while he did so he begged to tender to that gentleman the sympathy of the members of that section in his unmerited deprivation of his office of medical officer of health for Bradford. Dr. Heine thanked the meeting for this sympathy. With respect to the communicability of scarlet fever, he referred first of all to Dr. Klein's investigation, and observed that it had in no way been proved that the microbe which that gentleman had alleged to be the cause of scarlet fever in cows, could produce that disease in the human race. Scarlet fever had been very prevalent in Bradford, and as the medical officer of that city had power to isolate the sick, and to cause the shutting up of sheds where there was a supply of milk which was producing scarlet fever he had been enabled to study this question well of late in Bradford. He had seen fifty-five cases of scarlet fever, arise in one week in Bradford, but at that time there was absolutely no affection in any of the cows in the district. There had in all been four hundred and fifty cases of the disease in that epidemic. He had found that a great number of these patients were obtaining their milk supplies from one source, but on visiting the cow-houses of that milkman, he had found no trace of disease among the cows. In one case where a milkman supplied a certain number of customers, he had found a child lying sick with scarlet fever in the room where the milk cans were. In another case there was scarlet fever in the house of a milkman, but he refused to send his child into the hospital appointed for that purpose. That man supplied twelve hundred persons, and only one case of scarlet fever occurred among his customers. In the case of another man who supplied ninety families with milk, although there was sickness in his family, none of the customers were attacked. A farmer in the county also supplied many customers in Bradford, and in his house was a child sick from scarlatina, but no one was infected by the milk sent from that farm. From these facts he could not help thinking that it was not clear that scarlet fever was derived from cows suffering from the disease, and it was also likely that the disease was very rarely spread by milk.

Dr. Carpenter, of Croydon, was of opinion that

TUBERCULOUS MEAT SHOULD BE CONDEMNED

as unwholesome. A man in Croydon had been much aggrieved when his meat was condemned as being unfit for food, and called in several witnesses from London to show how commonly pearl disease was found among cattle slaughtered in London. In some instances as many as eighty per cent. of all cattle killed had been found to be tuberculous. Fortunately, cooking appeared to be capable of taking away the danger arising from the presence of the germ of tuberculosis contained in such meat. With respect to the question of scarlet fever, he would like to make some remarks which might be suggestive to those who had mysterious outbreaks of scarlet fever to account for. Scarlet fever had broken out in a school near Blackheath, and the school was at once closed and the children sent home. The fever still continued among these same children, but did not spread to other children. On inquiry he found that this school communicated with the great sewer at Deptford, and was the only opening into that sewer for nearly a mile. The children in that school had for some time been exposed to the influence of the fetid air from that drain, and their health had been lowered thereby, and they had become fitted to receive the scarlatinal germs, while children in their neighborhood escaped.

Professor MacFagin, of Edinburgh, adverted to the communicability of tape-worm from animals to man. With respect to the communication of anthrax, that was a rare event in the case of human beings, although the disease was, of course, inoculable in both cases. He had no cognizance of the communication of anthrax to man by the eating of the flesh of cattle affected with the disease. There had been a small epidemic of anthrax near Edinburgh, and some cattle and twenty sheep had died from it, but no human being had been affected. With respect to scarlatina, a previous speaker had said that there was much evidence that scarlet fever might be communicated from cows to man, but he demurred to this statement. Within the last month, Dr. Armstrong, of Newcastle, had said he had failed to find any connection between the communication of scarlet fever by milk. With respect to Dr. Edington's discovery of the microbe of scarlet fever, he must remark that the cultures made by that gentleman had produced no effect when inoculated upon calves. As to tuberculosis, it was certainly a very common disease among cattle. He should, however, estimate that instead of fifty or eighty per cent., it would be more likely to speak of five per cent. of the cattle, since very few young cattle had pearl disease. There could be no doubt but that the identity of the two diseases had been established. Abdominal tuberculosis, however, was uncommon in the human species, which did not coincide with the hypothesis that tuberculosis was often obtained from the flesh of diseased animals.

Dr. McVail was of opinion that the evidence for scarlet fever originating in the cow was great. Professor Ane, in the case of the Hendon disease, had gone to the place far too late, and this invalidated his evidence.

Principal McCall, of Glasgow, asked whether tuberculosis could be communicated from food supplies. It was a very terrible thought to think that such a high percentage of cattle suffered from pearl disease; but fifty per cent. was far too high a figure to give for cattle slaughtered in Glasgow; twenty-five per cent. was far more near the truth; and tuberculosis was rarely seen, except in animals kept in byres where there was little ventilation, and where one cow infected its fellow. The cow-feeders blocked up the windows of their houses for cows, and thus spread the disease. Tuberculosis was much more infectious among cows than in the human race. In one case he had seen eleven cows with pearl disease out of thirty-seven slaughtered. Some of these were almost rotten, and yet they were giving milk supplies to the children of Glasgow. These, however, were exceptionally bad statistics. Tuberculosis sometimes occurred in animals of great value. In one case he had recently seen miliary tubercle in the bone, and abscess in an ox which had walked six miles to market, and was sold for £23. As to the communicability of scarlet fever from cows, he had seen one instance where cows had an eruption on the teats, and where scarlet fever was in the neighborhood. There had been falling of the hair from the whole body. A gentleman who examined the animal found a micrococcus in the blood. He had not made up his mind upon this point. Dr. Wharry said that it was out of the question to talk of a percentage of fifty, as applied to cattle slaughtered, as suffering from tuberculosis. Such cases only occurred in old cows. In Cumberland, hosts of cattle had no trace whatever of tuberculosis, and it was a mistake to talk about the disease being so very prevalent among cattle. He thought it unproved that any disease in the cow existed at all comparable with that of human scarlatina. He held that dairymen should be required to notify the presence of scarlet fever in their families.

Dr. C. R. Drysdale read a paper on

INDIGENCE AS A CAUSE OF HIGH DEATH-RATES,

in which he maintained that good ventilation and sewerage were not the only essentials to the health of a community. Insufficient food, shelter, and clothing were also potent factors in the causation of disease.

SECTION OF THERAPEUTICS.

Wednesday, August 8th—Second Day.

Dr. C. R. Drysdale read a paper on

THE SO-CALLED ABORTIVE TREATMENT OF SYPHILIS.

As early as 1701, a writer named Nicholas Andry alleged that all the virulent diseases were caused by the ravages of invisible beings, that syphilis was one of these diseases, and that the way in which mercury acted in the cure of syphilis was by killing these animalcules. This idea has been revived, and has received much countenance by the splendid discoveries of M. Pasteur and his coadjutors; so that it is possible that a real way of syphilization may be discovered, whereby some poison more inimical to the existence of the microbes causing syphilis may be introduced into the system, and thereby the disease may, like hydrophobia, be arrested in its progress. Has mercury or iodine the power to abort syphilis in its early days? That these substances are both capable of destroying germs outside the body is known from their action in destroying pediculi, the itch insect, and, in the case of mercury, in its power of preserving puerperal women from the invasion of disease-producing germs when used as local applications.

The value of iodoform in chancroid is well known. It is now alleged, as was before said by the late Mr. Solly, and this time by an unequalled observer, Mr. Jonathan Hutchinson, that mercury does possess this germicidal power, and that when small doses of mercury and chalk are given to a patient with hard sore, or the initial lesion of syphilis, it is rather easy to prevent all further symptoms of syphilis from appearing; in fact, it is not difficult to abort the disease. He contends that the reason why our predecessors failed to accomplish this is, because they gave so much mercury that the drug could not be given for any length of time, so that in the intervals some of the syphilitic germs again spread and multiplied. If this were verified it would indeed be a boon to the thousands who are destined to fall victims to that terrible disease. But before accepting this conclusion, it is well that it should be discussed, and all conflicting evidence explained away. Firstly, then, there were a number of comparative experiments on the treatment of syphilis, made by Professor Boeck, at the Christiania Hospital, which are narrated in his work "Recherches sur la Syphilis." That observer treated one thousand and eight cases of chancre by means of mercury, with the result that two hundred and forty-two of them, or twenty-five per cent., became affected with secondary eruptions. He then treated five hundred and twenty-two similar sores without mercury, and seventy-seven, or fourteen per cent., became affected. Both Professor Boeck and Professor Hutchinson are what is called unicists, *i.e.*, both of them believe that chancroids are mitigated chancres, or contain some of the properties of syphilis. This was not the view of the author of this paper, who considered that chancroid had as little to do with syphilis as scabies had to do with ringworm. In 1883, Sir Spencer Wells said, at a meeting of the Royal Medical and Chirurgical Society, that mercury was no preservative from secondary symptoms, and Dr. Diday, of Lyons, in 1882, read accurate notes of seventy-five cases of syphilis, forty-nine of which had been treated in the chancre period without, and twenty-five with, mercury (protoiodide pills). He also alleged that mercury in this form, given in the hard sore, did not prevent secondaries. The author, captivated by the germ theory of syphilis, had also, in the Rescue Society's Hospital of London, treated all his cases of syphilitic sore with doses of one-sixth of a grain of green iodide, and then with one-grain doses of mercury with chalk for lengthened periods; but had always been able to detect some slight symptom of syphilitic infection, such as roseola or mucous tubercles, on his patients. Of course, he admitted that his dose may not have been the right one.

Professor Isodor Neumann (*Wiener Med. Blätter*, 1886) has recently made a similar experiment, using inunction in the chancre period as an abortifacient. Although as many as 55 inunctions were made in one case, 80 in another, 32 in another, 33 in another, 55 in another, and 47 in another case, all the patients ultimately had mucous tubercles on the fauces. But Professor Neumann found that mercury hastened the disappearance of the chancre, and postponed the appearance of the secondary symptoms. So far, then, other observers do not appear to coincide with the conclusions of Mr. Hutchinson. A still more important allegation has been made by Professor A. Fournier, of Paris, *i.e.*, that by prolonged courses of mercury in the early period of syphilis the occurrence of tertiary syphilis may be prevented in a large number of cases. His colleague, Dr. Lancereaux, however, denies this, and Dr. Jullien's statistics show that most cases of severe tertiary syphilis at Paris had taken long courses of mercury. Dr. Keyes, of New York, holds that the best treatment of syphilis is by giving very small tonic doses of the green iodide, such as one-sixth of a grain, several times a day for months and even years, in all cases of syphilis. He contends that such small doses tend to increase the number of blood-disks, and the author of this paper can testify, from his own experience in the Rescue Society's Hospital, to the innocuousness of long-extended experiments with such doses. But as to whether they prevent tertiary symptoms is another matter, which it is difficult to decide about. No one, on the contrary, of any experience doubts the very great power of iodide of potassium over gummy deposits, either accompanied or not by mercury. Hence, in affection of the bone and soft parts in tertiary syphilis that drug should be liberally used, and inunction may be added in cases of cerebral syphilis, where every hour is of consequence to the patient. In short, the abortive treatment of syphilis admits of question, and hence, although mercury be used at all times in syphilis, it should be used in the small doses recommended by Hutchinson, etc., *i.e.*, in doses of one grain of mercury and chalk, hoping that this may tend to destroy the germ, or even nip it in the bud.

PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, May 18, 1888.

Dr. George F. Shrady, President, in the Chair.

Dr. George L. Peabody reported two cases of

CHLORATE OF POTASH POISONING

with demonstrations of specimens. [See Medical Record p. 57.]

Dr. A. H. Smith said that for many years he had used chlorate of sodium instead of chlorate of potassium, because the former salt was less depressing to the muscular system.

He thought that in certain forms of stomatitis the chlorate seemed to be of value locally applied. In prescribing the sodium chlorate it is necessary to be careful in writing it out or one will get chloride of sodium.

Dr. Peabody, in response to a question, said that he did not think that chlorate of potassium could under any conditions in the body liberate its oxygen. He did not agree with Dr. Smith as to the innocuousness of the sodium salt, but admitted that larger doses were required to cause toxic effects.

Dr. A. Brayton Ball read a paper entitled

SOME DIFFICULTIES IN THE DIAGNOSIS OF TYPHOID FEVER.

[See Medical Record p. 225.]

Dr. W. H. Draper thought that the statistics given by Dr. Ball proved what he thought to be a fact, viz.: that continued malarial fever was a very rare disease in this locality. He thought that the efficiency of quinine was an almost infallible test in distinguishing the two disorders.

Dr. A. H. Smith said that he had seen a good many cases where there were no abdominal symptoms or spots;

and he accepted such cases as typhoid. But if such cases terminate in five or ten days it is very hard to be positive as to the diagnosis. The speaker cited a case in point. Such cases approach very closely those that one sees in children, *i.e.*, cases of fever that come on suddenly and last only twenty-four or forty-eight hours. He thought that typhoid came on more rapidly now than used to be the case.

With reference to the diagnosis from acute tuberculosis of pulmonary type, he thought the increased frequency of respiration was an important fact.

Dr. Draper thought that many of these cases that apparently came on suddenly with a chill have really had prodromal symptoms.

Dr. Ball cited the case of a clergyman who preached on the day before his chill and had felt perfectly well up to the day of chill.

Dr. Kinnicutt spoke of an illustration of the complication of articular symptoms with typhoid fever. Dr. Kinnicutt could confirm the value of Ehrlich's test in diagnosticating the fever. The speaker added that he had recently seen a typical case of typhoid fever in a child four months old.

Dr. Gibney said that he had recently observed also a case illustrating the combination of articular symptoms with typhoid.

Dr. Robinson said, with reference to the class of ephemeral fevers such as Dr. Smith had referred to, that the French described them under the term synochal fever. He thought that the presence of free pigment in the blood was sometimes a help in the diagnosis of the malarial types of fever.

Dr. Dana reported the results of the

INTERNAL USE OF MENTHOL

in migraine and other painful disorders. He gave the drug in doses of gr. v. to gr. xx., ter in die, or every hour. It might be administered in capsules, or, better, in a twenty per-cent. alcoholic solution dissolved in a wineglass of hot water. It was particularly useful in attacks of migraine, anæmic headaches, and supra-orbital neuralgias. Sphygmographic tracings were shown illustrating the stimulant action of the drug on the heart.

Variolous Periostitis.—Four cases of variolous periostitis have been observed by M. Barié. The bones most frequently attacked were the left tibia, the radius, and the humerus. The periostitis generally appeared five or six weeks after the onset of the small-pox, and manifested itself first by severe pain, limited to one part of the skeleton. There was no redness or heat of skin; a sort of swelling, "hard œdema," might be found over the seat of pain, but no fluctuation. Probably its pathology is identical with the periostitis following on, or supervening in, typhoid fever.—*The Lancet.*

The Influence of Bromide of Potassium on the Elimination of Urea.—Dr. Cesare Agostini reports, in *Lo Sperimentale* for May, 1888, a number of experiments made to determine the effect upon the excretion of urea of bromide of potassium given in varying doses, and comes to the following conclusions: 1. Bromide of potassium slows organic metabolism, as is evidenced by the diminished elimination of urea which takes place during its administration. 2. Such diminution is not, however, proportionate to the size of the dose prescribed. 3. After prolonged use the organism becomes tolerant of the drug, and this effect is no longer observed. 4. But this tolerance diminishes or disappears upon the discontinuance of the bromide. The author believes that large and continued doses of bromide of potassium are compatible with perfect health, and that the emaciation and anæmia sometimes observed to follow its administration are due solely to the local action of the drug upon the digestive organs, and not to any permanent effect upon metabolism.

Correspondence.

THE IMPERFECT VAGINAL TAMPON.

To the Editor of The Medical Record.

When the host who was entertaining one of our statesmen apologized for the whiskey, saying that it was poor, the guest objected and said that it might be poor for whiskey but no whiskey could properly be called poor. So when Dr. Ostrom, in The Medical Record for September 8th, objects to the qualifying adjective which I employed when describing a vaginal tampon in a previous number of the journal, I am tempted to respond and to say that, while the tampon in question is not perfect as a universal corrector of the ills of woman—thereby differing from Lydia Redham's compound—it is, nevertheless, as nearly perfect in the way of tampons as anything that I expect to employ. It is easier to apply the tampon with a speculum at the bedside than it is to apply it with the pen at the desk, and I probably in the former article failed to give the idea that, while the apparatus described was typical, its varieties may differ widely. It may be made with projections and curves; it may be round or flat, hard or soft, large or small, and yet present the essential features of the type. The skill of the maker of any given variety of the tampon in winding it into shape with the silk thread will determine the degree of comfort which the patient may expect to receive from its application.

Concerning the employment of Wylie's solution, I have met with cases like Dr. Ostrom's in which the mixture seemed to act as an irritant, but, on becoming *en rapport* with the patient and increasing or decreasing the relative amount of some one of the ingredients, I have not had difficulty in making the solution act as a helper, and it usually acts in a very decided way.

I have usually noticed that unpleasant results following the application of the tampon and the solution in question were due to some fault in the method of using them, and a later experience has enabled me to avoid a repetition of earlier errors.

A man can put on his own hat a good deal better than anyone else can do it for him, and descriptions galore would not help any; and a physician can use his favorite medicines and apparatus with greater satisfaction than others can derive from their use in the same ways.

Robert T. Morris, M.D.

133 West Thirty-fourth Street, N. Y.,
September 10, 1888.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 16 *to September* 22, 1888.

By direction of the President, the Army Retiring Board at San Francisco, Cal., convened by War Department order dated July 20, 1886, published in S. O. 168, July 22, 1886, from Headquarters of the Army, is dissolved. Par. 1, S. O. 217, A. G. O., September 18, 1888.

By direction of the Acting Secretary of War, the leave of absence granted Major Alfred A. Woodhull, Surgeon, in S. O. 148, June 27, 1888, from this office, is extended fifteen days. Par. 14, S. O. 218, A. G. O., September 19, 1888.

By direction of the Acting Secretary of War, Captain Robert J. Gibson, Assistant Surgeon, is relieved from duty at Alcatraz Island, Cal., and will report in person to the President of the Army Medical Examining Board, New York City, on October 16, 1888, for examination for promotion. On completion of his examination Captain Gibson will proceed to Fort Trumbull, Conn., and report for duty to the commanding officer of that post, reporting by letter to the commanding general, Division of the Atlantic. Par. 13, S. O. 217, A. G. O., September 18, 1888.

By direction of the Acting Secretary of War, First Lieutenant Edward R. Morris, Assistant Surgeon, is relieved from duty at Fort Thomas, Ariz., and will report in person to the commanding officer of Fort Shaw, Mon., for duty at that post, reporting by letter to the commanding general, Department of Dakota. Par. 14, S. O. 217, A. G. O., September 18, 1888.

Official List of Changes in the Medical Corps of the United States Navy for the week ending September 22, 1888.

CABELL, A. G., Passed Assistant Surgeon. Ordered to the Naval Hospital, Chelsea, Mass.

BAKER, J. W., Passed Assistant Surgeon. Detached from the Naval Hospital, Chelsea, Mass., and to the Palos.

LEACH, PHILIP, Passed Assistant Surgeon. Detached from the Palos, and granted six months leave abroad.

SIMONS, M. H., Surgeon. Detached from Naval Academy and wait orders.

HARMON, G. E. H., Surgeon. Ordered in charge Naval Academy.

PICKRELL, GEORGE McC., Assistant Surgeon. Detached from the New Hampshire and to the Ossipee.

ARNOLD, W. F., Assistant Surgeon. Ordered to the New Hampshire.

HENRY, C. P., Assistant Surgeon. Detached from the Ossipee and granted sick leave.

CORDEIRO, F. J. B., Assistant Surgeon. Promoted to Passed Assistant Surgeon.

SPEAR, J. C., and RHOADES, A. C., Medical Inspectors. Placed on the retired list, September 14th.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 22, 1888:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	55	13
Scarlet fever	80	16
Cerebro-spinal meningitis	1	1
Measles	93	9
Diphtheria	44	12
Small-pox	3	0
Yellow fever	0	0
Cholera	0	0

THE STUDY OF MALARIA AT ROME.—A proposal of Professor Celli's, to establish in the malarious region that encircles the city of Rome a number of meteorological stations for the special study of the fever and its climatic conditions, has been favorably received by the Central Meteorological Council and by the Board of Public Health at the Ministry of the Interior.

CRAMPS IN THE LEGS.—Dr. R. W. St. Clair, writing on this subject in *The Medical Age*, says that when he has a patient who is subject to cramp, he always advises him to provide himself with a good strong cord. A long garter will do if nothing else is handy. When the cramp comes on, take the cord, wind it around the leg over the place that is cramped and take an end in each hand and give it a sharp pull—one that will hurt a little. Instantly the cramp will let up, and the sufferer can go to bed assured that it will not come on again that night. For a permanent cure he recommends galvanism, the negative pole being applied over the seat of the cramp, the positive pole on the thigh.

MEDICAL INCOMES IN KANSAS CITY.—A certain prominent physician of Kansas City asserts that he is making $20,000 a year, cash, from his practice. What was the name of Sapphira's husband?

THE MANAGEMENT OF PUBLIC HOSPITALS.—A correspondent, named Mrs. Rees, writes to the *Epoch*: "It has been my lot on three several occasions to experience the hospitality of public institutions, twice as patient for many months in paying wards, once in close attendance upon a dying child. In each one of these cases my personal experience has been the same—devoted attention by nurses and attendants, experienced skill, more or less valuable, on the part of the physicians, unutterable discomfort from details owing to careless or wilful mismanagement by the hospital warden, matron, or superintendent. For the guidance of those interested in the question as to why constant complaints arise against public institutions, I will cite one instance in my own experience. Its value for the public lies in its absolute truth. I spent fifteen hours in the accident ward of one of New York's best hospitals, by the bedside of a child who had been run over. The greatest sympathy was felt in the case, and all the resources of the hospital were called into requisition. The sufferer was placed upon the only vacant bed in the sudden accident ward, and surrounded by some six or eight young students, the house-surgeon apparently in command. By the light of a tallow candle they made the examination, and squabbled a good deal over it. One of them plumped himself down several times upon the bed, but desisted upon my remarking that had he ever suffered he would probably be more careful. After the examination had been conducted to their satisfaction (their comments having been made without the slightest regard to the fact that the patient was perfectly conscious and that his mother was in attendance), they withdrew, first laughing and then squabbling, but principally interested in a jocular conversation with a bright-looking nurse. I suppose my looks betrayed a little astonishment, as when they had left the ward the house-surgeon (a refined and intelligent young man, to whom I owe a deep debt of acknowledgment for unvarying courtesy during the night that followed) came to me and said, 'I hope you will excuse our roughness here; the fact is, we *are not accustomed to patients of your class.* I have spoken to the nurse, and she will be quieter in the future.' I replied to the effect that I imagined patients of all classes felt much alike. We settled down to a night of anxiety, in anticipation of amputation on the morrow. The patient was perfectly conscious; my own concern was to shield him as much as possible from the distressing sights and sounds inseparable from a crowded ward. One instance of my care will suffice. I spent my time in *picking bed-bugs off the pillow and mattress* before he should see them. The night orderly stood for some minutes watching me. Then he said apologetically: 'This 'ere bed ain't been slept in a great while. 'Tis the hot bricks brings 'em out (it was a frosty night in November); but, you see, we don't often have gentlefolks here!' Even in that hour of anxiety I could not suppress a smile. Are only gentlefolks worthy of quiet and the absence of vermin? At six o'clock the night nurse, leaving the ward, withdrew the hot bricks, and no others were brought until after eight o'clock, when the visiting surgeon made his rounds. It was a very cold morning and the patient was chilly. These are very simple facts. The question is, who was to blame for them? I could multiply them, but it is not necessary. They suffice to point the moral: *It is the things for which no one is responsible* that render our institutions a reproach to our intelligence."

URETHRAL IRRITATION IN THE MALE AS A SOURCE OF DISEASE.[1]

By LE GRAND N. DENSLOW, M.D.,

PROFESSOR OF GENITO-URINARY DISEASES AND DISEASES OF THE SKIN AND SYPHILIS, ST. PAUL MEDICAL COLLEGE, ST. PAUL, MINN.

Nearly thirty years ago, Dr. Marshall Hall claimed that irritation of peripheral nerves would produce, through centric disturbance in the spinal cord, many disorders of the economy of apparently distant origin. Since that time his claim has been sustained by thousands of cases observed and reported, bearing upon almost every organ of the body, so that to-day it is no longer a theory, but an accepted fact, based upon an overwhelming amount of clinical proof.

We know that the gynecologists, oculists, aurists, neurologists, and, lastly, but not least, the rectal surgeons have not been behindhand in their appreciation of this; thereby ridding humanity of an almost incalculable amount of pain and suffering, with both honor and profit to themselves.

On the other hand, the general practitioner, together with the general and the genito-urinary surgeon, has, with a few rare exceptions, not given this matter of reflex irritation sufficient attention; nor do I think have they appreciated the extent of the untrodden ground yet to be explored by the study of this subject as an etiological factor in both functional and secondary organic diseases that come under their observation.

This being the state of affairs, the opinion of a few of our most eminent physicians may not be amiss at this point.

Sir Henry Thompson says: "I have given complete relief to distressing symptoms of very long continuance, the cause of which was not suspected, by dividing an internal meatus. I have met," he further states, "with three marked examples of a similar kind, in which the very simple operation necessary was followed by complete disappearance of urinary difficulties, which had been long regarded as of an extremely obscure character."

M. Civiale writes: "Independent of its local sensitiveness, the urethra possesses another kind which may be termed sympathetic; also, when this sensitiveness is aggravated it may awaken sympathetic responses in every organ and function of the body." In many cases sympathetic phenomena were manifest in the lower extremities, particularly in the soles of the feet. Again: "It is not rare to observe that slight encroachments upon the urethral calibre induce marked difficulty in micturition; those at the meatus having this effect not less than those located further in." Again: "Strictures seldom exist for a long time without exciting a series of disorders of the genito-urinary functions, and consecutively in remote parts of the body; among them gleet, retention of urine, and difficult micturition. That which has struck me forcibly in dividing a meatus, only slightly contracted, is the sudden and complete change effected in the general condition of the patient. The constriction which seemed barely to impede the flow of urine is no sooner divided than all morbid symptoms vanish. The urethral walls which were rigid, hard, and unelastic, immediately recover their normal condition. An effect so prompt, through means of which the significance is plain, shows that the slightest obstruction in the urethra is able to produce the gravest symptoms, local and general." Civiale also states that obstructions in the urethra will set up reflex irritation sufficient to produce paresis.

Otis' opinion is so well known that it is hardly necessary to mention it, but to him is due the honor of being the greatest investigator and enthusiast in this field in this country.

Beard says, in his book on sexual neurasthenia: "What lacerations of the cervix and perineum, irritations, congestions, and displacement of the uterus and ovaries are to many female nervous symptoms, such are phimosis, redundant prepuce, varicocele, irritable testes, urethral contractions, and, above all and pre-eminently, irritation and congestions of the prostate and prostatic urethra, to many male nervous symptoms."

Hammond, in his book on impotence in the male, cites a large number of cases where grave nervous disturbances, such as loss of memory, melancholia, and general neurasthenia, were directly due to irritations in the urethra, and were generally relieved by appropriate treatment.

Beard records some forty-three cases illustrating so-called neurasthenia, in almost all of which excessive venereal indulgence is set down as the cause. These cases cover a wide range and are illustrations of almost every class of disease set down in the following table. He believed that spinal and cerebral exhaustion was the source of most of these troubles; whereas, undoubtedly, the urethral irritation was the true seat of the disease, as many of them were promptly relieved by attention to this particular locality.

Gross cites several interesting cases of mental depression that were relieved by attention to the contractions in the urethra.

Brown-Séquard, in 1874, related a very interesting case that presented all the rational signs of advanced cerebral disease, one he considered quite hopeless, that was relieved by an operation for phimosis, and the treatment of an inflammatory condition of the glans penis. To quote his own words, he said: "So rapid was the recovery that within six weeks from the date of the operation he presented himself at my office perfectly well in every respect."

Dr. Sayre, in 1870, before the American Medical Association, reported several cases of partial paralysis of the lower extremities, due to the same cause. He says of one case, from the very date of operation the child began to improve, and without other treatment made rapid and complete recovery. In another of his cases of paralysis of the lower extremities associated with urethral irritation, causing dysuria and painful erections, appropriate surgical treatment resulted in a complete recovery in six weeks.

From what has already been said, the importance of the subject is so apparent that I will offer no apology for calling your attention briefly to this almost inexhaustible subject. So far as I know there has not as yet been any definite classification of disorders due to this cause. I would therefore submit to you, this evening, a crude one with a few illustrated cases. I am well aware that it is very defective, and that in many instances a case could, with equal propriety, have been placed in any one of several, or in more than one class; the attempt has merely been to place them where they might be considered from the stand-point of the most prominent symptom, as a matter of convenience and aid to their study.

---

[1] Read before the Minnesota Academy of Medicine, at Ryan Hotel, St. Paul, Minn., March 3, 1888.

CLASSIFICATION.

1. Cerebral.......	Headache.		Anthrophobia.
	Mental depression.		Epileptiform convulsions.
	Defective memory.		
	Melancholia.		
	Excessive irritability.		
	Brain exhaustion.		
2. Spinal.........	Partial paralysis.		
	Formication.		
	Pain,	Back.	
		Testicles.	
		Urethra.	
		Legs.	
3. Cerebro-spinal..	Cardiac irritability.		
	Dyspnœa.		
	Sweating of the hands and feet.		
	Syncope.		General alopecia.
4. Sympathetic....	Acne.		
	Congested conjunctiva.		Functional eye troubles.
5. Digestion......	Dyspepsia.		
	Anæmia.		Impaired nutrition.
6. Genito-urinary..	Gleet.		Spasmodic stricture.
	Urethritis		Impotence.
	Irritable prostate.		Cystitis.
	Prostatorrhœa.		Organic disease of the kidney.
	Spasm of the ureters.		Uræmia.

Heading the list, in the first class, we have headache, well illustrated in the case of a young man who came under my observation about a year ago, suffering from a slight gleety discharge, which had existed for several months. He had had no venereal trouble. Upon examination I found a highly sensitive condition of the urethra for the first inch, associated with a contracted meatus. This was slit up to the normal size, with the result of curing the gleet before leaving for home, which he did in a few days. He remarked to me that for months he had been annoyed by very severe headaches, occurring almost daily and which frequently incapacitated him for business; but that since the operation they had ceased. At my request he has since written me at intervals of several months, each time stating that he has not had any recurrence of his head trouble.

Mental depression associated with anthrophobia and sensitive urethra is quite common. Such a case I now recall in which there was a sensitive urethra with a meatus measuring twenty-four, occurring in a prominent member of the bar of this city; there was great mental depression with excessive irritability and defective memory; to such an extent that he remarked that it was with the greatest reluctance he would now accept an important case. Division of the contraction was followed by complete relief from all these symptoms. I afterward learned that the patient had been suffering for some fourteen years with an aggravated case of acne of the shoulders and back; he applied to me several weeks afterward, stating his acne had disappeared, and wished to know whether, in my opinion, the treatment could have had anything to do with it. I think these two cases are particularly important, proving as they do in both instances that the moral effect of the operation, as has been claimed by some, could not by any possibility have influenced the cure in either case; either the headaches or the acne, as they were not spoken of at the time.

A case of well-pronounced melancholia I have never treated in this manner, but Hammond and Otis both have recorded them.

I have met in this city a very pronounced case of what might be called brain exhaustion, in a merchant, a very hard worker, who applied to me for relief, complaining of a loss of seminal fluid during defecation, accompanied by a constant "tired feeling," as he expressed it; and inability, without effort, to conduct to his satisfaction as formerly, a large business, requiring considerable mental activity. Although there was no loss of memory, his head, as he said, felt tired. I found a small meatus, together with several deeper contractions, and an exquitely sensitive condition of the entire urethra. The meatus was divided, together with the other strictures, with great relief, but the symptoms did not entirely disappear until a second operation, as a slight contraction took place after the first.

In this connection, I would say that I would not despair of giving relief from any symptom that appeared to have its source in the urethra, until the canal is perfectly free from obstructions and had regained its normal sensibility.

Otis has reported the cure of a patient suffering from epileptiform convulsions by the simple passing of sounds.

The following case, occurring in my own practice, will speak for itself: June 15, 1885, G——, printer, had gonorrhœa seven years ago, lasted a month before he was entirely well; had connection with dissolute women several times every night for two weeks. About that time, one day he fell in a fit, biting his tongue, etc. These attacks have occurred almost daily, and sometimes every day, until the present time. He has frequently fallen from his stool while at work. His last attack occurred yesterday; the stream of urine very small. Upon examination, normal urethra should be 34, meatus only 29, strictures at 2, 3, 4½, and 5½ inches; the latter only admitting a number seven. Following the examination, he had severe attack just after leaving my office. The next day I divided the meatus and introduced French bougies for the next week, for the relief of the lower stricture. His general condition was so bad that I refused to perform urethrotomy at that time. Within a few days a twenty-two could be easily introduced in the bladder, and although I treated him for a number of weeks, he did not during that time have another epileptiform attack. Finding that he was relieved he dropped out of notice, as he refused operation which I considered necessary for a radical cure.

In the second class, commencing with partial paralysis of the lower extremities, I reported a case in THE MEDICAL RECORD some time ago, occurring in my practice in this city, in an apparently very strong man. There were several strictures in the pendulous portion of the urethra, together with contracted meatus. He was entirely relieved after the first operation.

I have already spoken of very pronounced cases reported by Sayre and Otis.

Pain is a very common symptom, and as to its situation, I think it occurs in the legs most frequently. It is generally referred to the inner aspect of the thighs, occasionally reaching as far as the knees, and not infrequently the feet. The next situation is the back; generally in the lumbar region, radiating over the buttocks and along the sides. The third and most frequent is in the testicles; and the last, and consequently the one the cause of which is most likely to be overlooked, is the urethra itself. When occurring here it is not generally such as would be produced by an active inflammatory condition, but rather neuralgic in its character. I have classed with the latter the pain, or rather the pressure and weight, frequently complained of in the perineum.

Formication is generally referred to the scrotum or inner aspect of the thighs.

Otis, Beard, and Hammond all reported cases of cardiac irritability and dyspnœa. It has not been my good fortune to meet with these symptoms.

In the next class that I have called sympathetic, we have sweating of the hands and feet as the symptom complained of. This very frequently amounts to such an inconvenience as to need attention. I have recently met with a case of sweating of the hands that was greatly relieved by division of the meatus, but as there has been some contraction following the operations, the cure may be expected when this difficulty is overcome, as it probably will be after another operation. In this connection it is worth mentioning that occasionally there is a case where contraction is prone to occur to such an extent as to require several operations; these, fortunately, are rare, one operation generally sufficing. I do not attempt to explain this complication, as all cases receive the same after-treatment.

Otis reports a case of complete unconsciousness following the passage of a sound. I have frequently noted great pallor and prostration under similar circumstances.

Acne is undoubtedly, in many instances, caused and kept up by an abnormal condition of the urethra. Sherwell, of Brooklyn, was the first to demonstrate this, in a paper read before the American Dermatological Society some five years ago, when he reported two severe cases cured by the mere passage of the sound, in which no venereal disease had occurred and where only a sensitive condition of the deep urethra existed. Since that time it has been my privilege to meet numerous cases where relief was afforded by attention to the genitals.

Congestion of the conjunctiva, and also numerous functional disorders of the eye, are known to be produced by venereal excess, probably from the fact that this would cause a congested and abnormally irritable condition of the prostatic urethra.

A very interesting case of general alopecia which came under my observation is worthy of special mention. S——, aged thirty, single, no venereal disease. During the past year the hair, which is of a very extensive growth over the entire body, has been falling rapidly; upon removing his underclothes they are found to be lined with fallen hairs. The skin over the entire body is, to all appearances, in a perfectly healthy condition. Thinking the trouble must be reflex, and in lieu of any other definite knowledge of the causation of this disease, I examined the urethra and found it normal, with the exception of excessive sensitiveness in the prostatic portion. From this time the sound was passed every other day. On March 1st, two weeks after treatment commenced, a very perceptible diminution in the number of hairs falling was noted. On March 15th, or one month after commencing sounds, but few hairs could be found on the clothing. On March 31st, after six weeks' treatment, the hairs of the entire body were firmly embedded and none could be found on the clothing. In September of the same year, five months after seeing the patient, he reports that he has had no return of his trouble. This is the first and only case ever reported where general alopecia was treated through the urethra. The result followed the treatment so rapidly, and proved so effective, that I will leave others to form their own opinion as to the cause of the trouble in this individual case.

The next class I have placed under digestion, and it is as yet, I think, a *terra incognita*. It comprises a group of so-called dyspepsia, anæmia, and impaired nutrition; or, if we may allow the term, cacotrophy. Several of the writers mentioned, more especially Beard, allude to dyspepsia as the result of urethral trouble.

The last class is genito-urinary. Where these organs are directly involved the true cause has, as a matter of course, been most frequently recognized. However, where the conditions are rare, but few, and in some instances individual cases only, are upon record. The relation of gleet and stricture is well known. But where a slight contraction of non-venereal origin is associated with gleet, it is not so frequently recognized. I have met with numerous cases where a catarrhal condition of mucous membrane of the urethra existed sufficient to produce a very susceptible discharge, which was undoubtedly kept up from this cause alone. Irritable prostate and prostatorrhœa are very frequently associated with irritability due to contractions in the anterior portion of the urethra. Otis particularly refers to this, and I could well attest it with cases.

Spasmodic stricture is a frequent accompaniment of the condition just mentioned, and I believe that many deep urethrotomies have been performed where division of the meatus or other contractions would have sufficed. It is unnecessary here for me to more than refer to the celebrated discussion on this subject that occurred a few years ago between Dr. Sands and Dr. Otis. In fact, the knowledge of this within the last few years has reversed the statistics as to the seat of the relative frequency of organic stricture. Formerly the greater number were thought to occur in the deep urethra, and to decrease in number toward the meatus, until Otis demonstrated that exactly the opposite state of affairs existed.

Of impotence I have had numerous instances where the division of the meatus was followed by prompt recovery. I will cite but one case where the history will show that all other cases can be eliminated: O——, aged forty-two, married, good habits, uses neither liquor nor tobacco, in perfect health; complains that he has been impotent for eight years, and that the condition came on gradually. (I mean by impotence, entire absence of erection of the penis, and total inability to introduce the organ within the vagina.) Upon examining the meatus, where the normal condition should have measured thirty-four it was only sixteen; otherwise urethra was normal and not in the least sensitive. The meatus was incised to thirty-five. That same evening an erection occurred, and the patient within ten days was pronounced cured This occurred five years ago. I have recently heard from this patient, and he assures me that at present there is very little indication that further treatment for his old complaint will be necessary.

Under cystitis I will refer to the histories of two cases; one occurred in the practice of Sir Henry Thomson, the other with Dr. Otis. As to the former case, "Sir Henry J——, aged thirty-four, suffering from painful, prolonged, and frequent micturition for five years, compelled to pass water from three to five times every night, and every two hours during the day. Has severe pains in the back and loins, and general ill-health; urine purulent and alkaline; habitual retention and partial engorgement of the bladder. Upon examination of the meatus, the seat of a cicatrix, due to a former chancre, admitted only a small probe; the opening was enlarged by incision and twelve ounces of urine drawn off, although he had just passed water. The relief was almost instantaneous; in a week it was complete. He has had perfect immunity from his urinary complaints ever since."

The report of Dr. Otis' case is as follows: "Age sixty-four; general good health; has been obliged to urinate almost hourly for the past ten years; strain small. Within three weeks began to suffer pain from the straining in passing water. Urine bloody and loaded with pus and mucous; was unable to attend to business. Prostate normal; meatus twenty-four; this was incised to thirty-one and no further obstruction of the bladder found at this time. Further examination for calculus was made by Drs. Otis and Marion Sims. The day following the operation he could hold his water for two hours and all the pain had ceased. Twelve days after the operation the pus had entirely disappeared from the urine; he could ride and walk without discomfort; had resumed his business and was not obliged to void urine oftener than every three hours."

These cases are sufficient to demonstrate the grave conditions that may be set up in the bladder from an apparently slight cause. Knowing, as we do, the short step from an aggravated cystitis of this character to organic disease of the kidney, it seems hardly necessary to demonstrate further possibilities in this direction; however, I cite one case that Dr. D. C. Black has noted: "Spasm of the bladder occurring from sympathetic irritation from the urethra, that resulted in complete closure of the orifice of the ureters, producing retention of urine in the ureters and pelvis of the kidneys." Dr. Otis also speaks of such a case, where he believes that death resulted from uræmia, due to the rude introduction of the catheter through a narrow stricture in the anterior portion of the uræmia; forcible and painful contraction of the bladder followed immediately with complete suppression of urine.

and the patient died uræmic. Twenty-four hours after, on post-mortem, the bladder was found empty, with the exception of a few drops of blood and mucous. It was closely contracted and free from disease; the ureters were normal; the kidneys were engorged with blood but gave no evidence of disease.

I have presumed upon your time to this extent with this array of facts (the limits of the paper not allowing of more than a brief mention in any individual class of cases), in the hope that it might arouse a further interest in the importance of a more thorough and systematic study of the conditions under consideration, and hoping that it might elicit a discussion that will add to our now comparatively meagre knowledge of the subject.

SULFANOL—THE NEW HYPNOTIC.

By B. SACHS, M.D.,

NEW YORK.

The medical public has come to look with suspicion upon every new hypnotic, and the more highly a drug has been praised for its hypnotic qualities the more sceptical we are certain to be. This is not unnatural in view of the many disappointments most of us have experienced with paraldehyde, urethan, amylen-hydrate, hypnone, and the like. Sulfanol is the latest applicant for medical favor, and appears to possess qualities which entitle it to a fair trial.

The main facts regarding sulfanol are already well known; the articles of Kast,[1] its discoverer, of Rabbas,[2] of Schwalbe,[3] and of Wendt,[4] have informed us that it bears the beautiful chemical designation diaelthylsulfondimethylmethan; that it belongs to the group of disulfons; that in doses of 1.0 to 3.0 or 4.0 it has a decidedly hypnotic action, and that it differs from other hypnotics, not to say narcotics, in restoring the natural desire for sleep. The experience of the German authors mentioned above has been highly satisfactory, even Schwalbe obtaining good results in sixty-six per cent. of his cases.

My own experience with sulfanol is limited to about sixty trials on fifteen patients.[5] These cases include a considerable variety of troubles, and a fair number of those troublesome cases of functional insomnia on the treatment of which I wrote a short article[6] about a year and a half ago. Limited as my experience has been, it is sufficient to show that this new hypnotic is a valuable addition to the Pharmacopœia, but that it is not infallible; and what drug is? The drug was administered, as a rule, in 2.0 doses, to be taken one-half hour before bed-time.

The following are a few of the histories (condensed) of patients in whom the drug was exhibited. I place the cases of functional insomnia at the head of the list.

CASE I.—J. R——, male, aged forty-seven, merchant; general neurasthenia from overwork and over-indulgence in alcohol and tobacco; has not slept well during the past year; is extremely restless and has heavy dreams; marked tremor of the tongue and fingers; knee-jerks lively if not exaggerated; severe palpitation (fatty heart); has been under treatment since June 3, 1888; was given no hypnotics until August 13th; took two grammes one-half hour before bed-time; was asked to take sulfanol on alternate nights; reports that he sleeps from twelve, midnight, to 6 A.M., without awaking, after taking powder; other nights quite as restless as before; has taken powders six times.

CASE II.—A. S——, merchant from Texas, aged forty-one; man of good habits; not addicted to alcohol or tobacco; no sexual excesses, but excessively hard work for years; has not been sleeping well for many years; never more than three hours' sleep; statement corroborated by his wife. August 21st, was given 2.0 sulfanol; reports that he has slept better than in five years; refreshing sleep, no dreams; has taken powder five times on successive nights, never sleeping less than eight hours after taking powder. Has gone South, with instructions to take powders if absolutely necessary.

CASE III.—L. V. H——, manufacturer, aged thirty-nine, hard worker and excessive sexual and tobacco indulgence; all symptoms of spinal neurasthenia; in addition, troublesome insomnia for two years past; 2.0 sulfanol one-half hour before going to bed sufficient to induce sleep for six hours, refreshing and without dreams; no headaches on awakening; three trials; insists on discontinuing drug from fear of contracting habit.

CASE IV.—G. F——, tobacco merchant, aged about forty-three, under treatment for a year or more for "tobacco heart." Met with severe accident (fell down elevator shaft), but escaped with contusion of hip and knee; severe nervous shock; complained of great pains for first three days; did not sleep a wink the first night after accident; second and third nights slept five hours continuously each night in spite of pain, which continued during day-time. Drug discontinued.

CASE V.—Miss K——, aged twenty; general nervousness and anæmia due to chronic intestinal catarrh; is wakeful all night (mother states that patient never sleeps more than two hours all told during night); sulfanol given in 2.0 doses three nights in succession; no improvement in sleep; drug discontinued. General condition has now improved; sleeps better.

CASE VI.—Miss F——, aged thirty-five; under treatment for several years for all sorts of neurasthenic and hysterical symptoms; has attacks of neuralgic pain all through body; these attacks most apt to come on at night; has frequently taken chloral, morphine, and other narcotics with little success. Complained of insomnia (without pain) while in mountains; was given powders of 2.0 sulfanol; slept well (five hours) first three nights; after that, drug lost its effects entirely.

CASE VII.—Mr. Fl——, aged forty, merchant; overwork and excessive sexual indulgence; symptoms of general neurasthenia, including sleeplessness. Has made three trials of sulfanol, and finds that refreshing sleep makes quite a different man of him; sleeps all night (about six hours). Further cases of this sort need not be given in detail. No disagreeable after-effects were noted in any of the above or in similar cases.

CASE VIII.—Mrs. J. N—— (Polyclinic patient), aged fifty-five, widow; mental depression with insomnia; headaches; loss of appetite; is afraid that sleeplessness will affect her mind. Slept well three nights after taking sulfanol (2.0) each night. Not heard from since.

CASE IX.—Mrs. K——, aged fifty-five; married thirty years; several children; one epileptic attack in early childhood; has had periodical spells of melancholy depression every two years for the last twenty-three years. Each spell lasts about fourteen days, during which time patient does not sleep at all; is restless and fearful lest she should become insane; tædium vitæ; has made one suicidal attempt during one of these spells a few years ago; is now (September 5th) in a similar attack; no hallucinations or delusions, but generally depressed, uneasy, and of slow mental action; tells her tale with reluctance; is averse to taking drugs, as they are all poisonous; was finally induced to take sulfanol, 2.0; did not sleep more than three hours; was given a second powder of same dosage on awaking and then slept seven hours continuously, but next morning woke up feeling dizzy and heavy in head—this feeling passed away during day;

[3] Deutsch Med. Wochenschrift, No. 18, 1888.

[4] New York MEDICAL RECORD, May, 1888.

[5] The drug is still very expensive, the usual dose, 2.0, costing about twenty-five cents; for this reason I have prescribed it in private practice chiefly, and have been able to test it upon one patient only in my department at the Polyclinic. It was originally manufactured by Bayer, of Elberfeld, but another preparation by Riedel, of Berlin, is now in the market. Riedel's preparation looks better, but I am not willing to state that one is superior to the other, both preparations having exhibited the same qualities.

[6] Medical News, May 18, 1887.

second night could not be induced to take powder, and was as restless as formerly (husband's report); has taken powder four times more, one powder each night being sufficient to procure five hours' sleep. Two weeks later patient was much improved; is evidently "out of her spell" again. Hyoscyam., gr. $\frac{1}{100}$, was tried twice; "sleep not as good nor as long," was the report.

Case X.—J. D——, aged sixty, clerk; severe pain, accompanying herpes zoster, along entire distribution of ulnar nerve; insomnia in consequence of pain; tried sulfanol, 2.0, repeated after three hours, two nights in succession—no effect whatever; third day of treatment, pain undiminished; had to resort to morph. sulph., gr. $\frac{1}{4}$, dissolved in mouth; patient slept well (at least four hours continuously) and was kept on morphia.

Case XI.—Mr. C. L. G——, aged thirty-two; case of typho-malaria with fever temperatures up to 105°F., pulse varying between 90 and 110; no abdominal symptoms. Takes an average of twenty-five grains of quinine during twenty-four hours. Very restless in consequence of elevated temperatures. In addition to quinine and antifebrin (gr. v.), when fever rose above 104°F. patient has received 2.0 sulfonal nightly five days in succession late in evenings, and invariably procured at least four to five hours' sound sleep (nurse's statement). No headaches in the morning, and no perceptible effect upon quality of pulse; no gastric distress after taking powder. Patient was not ordered to take powders in third week of the disease, but was given leave to take powder if very restless. Has taken seven powders since, never more than one a night; drug appears to have lost some of its force. Of late patient has obtained not more than three hours' continuous sleep from 2.0 sulfanol. Larger doses were not administered.

These histories will, I believe, suffice to show what the virtues of sulfanol are, wherein it is superior to other hypnotics, and in what respects it is, to say the least, somewhat disappointing.

1. These cases prove that sulfanol is valuable in cases of functional (neurasthenic) insomnia. In those cases in which insomnia is often the most distressing symptom, it appears to justify the claim of its discoverer that it restores the natural desire for sleep, two grammes being sufficient to bring about this result; Cases V. and VI. being exceptions to this rule.
2. It is easily tolerated by the stomach; does not produce headache, except in large doses of 3.0 and more; has no effect upon the circulation, and can be given in cases of irritable and fatty heart, and apparently in cases of fever (cf. Cases I., IV., and XI.), in all of which respects it appears to be superior to other hypnotics.
3. It has very slight or no narcotic virtues.
4. With some patients the drug appears to lose its effect if frequently administered.

If a larger experience than I have had will prove sulfanol to be a safe hypnotic in fever cases all medical men will recognize it as a great boon. In the treatment of insomnia accompanying mental troubles its success is assured; in the treatment of neurasthenic insomnia it promises very well indeed, and the treatment of this trouble can be inaugurated by the exhibition of this drug; but if the condition is to be permanently cured I hold to what I stated in the paper referred to above: "We are in need, not of additional hynotics, but of more effective means of regulating cerebral circulation."

September 20, 1888.

Three Cases of Pseudo-hypertrophic Paralysis in one Family.—Dr. Carlo Borsari reports in his graduation thesis (Naples, 1888) the case of three brothers, Pastorelli by name, aged respectively six, eight, and eleven years, who were suffering from pseudo-hypertrophic paralysis. The cause of the affection could not be determined, as there was a clear family history of entire freedom from any nervous or muscular diseases.

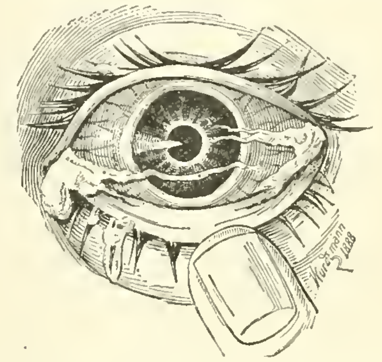
"THE TEA-LEAF EYE."

By H. V. Würdemann, M.D.,

Assistant Surgeon, Washington Eye and Ear Infirmary, Washington, D. C.

A peculiar pathologic condition of the eye exists among the lower classes of the South, especially the negroes. I refer to the affection usually known among physicians who have treated such cases as "The Tea-leaf Eye." The muco-purulent form is most common. Many of the laity believe that the best treatment for ocular irritation is a large poultice, preferably one of tea-leaves, applied upon the eye "*to draw out the disease.*" Even some of the medical profession, possibly of little experience in eye diseases, have advised such a poultice for conjunctivitis. Eyes that have been treated in this manner are easily recognized. The effects of one of these engines of destruction have but to be seen to be remembered for a lifetime.

The "Tea-leaf Eye" is on the increase as the hot weather approaches. The number of cases is at its maximum in midsummer. This may be accounted for by the fact that, when aided by outside heat, a poultice causes a much greater relaxation of tissue and increase in the contents of the blood-vessels. It sometimes happens that a poultice of tea-leaves, applied in mild cases of conjunctivitis, has actually produced a cure, by reason of its astringent properties. But if, as is usually the case, it has been frequently applied, or left on too long, it acts as any other poultice; the astringency is counteracted by the irritant and relaxing qualities. This is of course aggravated by the higher temperature of summer.



The Tea-leaf Eye at stage of Conjunctival Inflammation. (From nature.)

The most common symptoms produced by the poultice, when the ill effects are felt, are increased irritation, photophobia, lachrymation, and congestion. The vessels of the conjunctiva, especially the ocular, become engorged. The posterior conjunctival arteries and veins are first affected, then the deeper vessels, as the epi-scleral branches of the anterior ciliary vessels and epi-scleral plexus of veins; often ecchymoses are formed in the sub-conjunctival tissue. Then chemosis begins, and the ocular conjunctiva presents a pathognomonic, brick-red appearance. The blood-vessels are not so distinct as in catarrhal conjunctivitis. The exudation is characteristic, being muco-purulent, the mucus being in greater quantity and occurring in stringy masses, which are often seen upon the cornea. The small amount of exudation in comparison to the great congestion and chemosis is notable. The swollen conjunctiva encroaches upon and extends over the limbus, as in a typical case of purulent ophthalmia. The swelling gradually extends to the palpebral conjunctiva, though it is here less in amount. The lids in some cases become so greatly swollen that they cannot be opened or everted except by force.

If the poultice is still regularly applied, the inflammation extends and destructive changes occur, such as purulent infiltration of the corneal tissue, which may result in sloughing of the entire cornea. Inflammation being now of a high degree, this condition follows the course of purulent ophthalmia, resulting in inflammatory changes in the cornea, uveal tract, retina, choroid, etc.; in fact, a pan-ophthalmitis is quickly developed.

Patients usually apply for treatment when the conjunctival inflammation is at its height; luckily for them, before corneal infiltration has progressed to any great extent. In nearly all cases the eye is saved by treatment, and brought back to its normal condition in from one to three weeks. The illustration represents a typical case as well as is possible in black and white.

The treatment usually followed at the Washington Eye and Ear Infirmary has been much the same as for purulent ophthalmia. The utmost cleanliness is observed by careful syringing with lukewarm water. Solutions of cocaine and atropine, cold compresses, varying solutions of silver nitrate, leeches to the temples, and rest in a darkened room. Care has also been taken to warn patients of the contagious character of the exudation. The use of suitable laxatives and frequent bathing are of course advised. The after effects, as keratitis, choroiditis, etc., are treated by the usual remedies.

Cases occur throughout the year, but the following from the Infirmary books for July, 1888, are typical.

CASE I.—July 3d, W. S. H——, colored male, aged twenty-three, field hand on tobacco plantation, ignorant and uncleanly. Pan-ophthalmitis followed by leucoma. History: In early part of June "caught cold" in both eyes and applied a tea-leaf poultice which was renewed several times; no gonorrhœa. Present condition: Great photophobia and lachrymation, chemosis, and congestion. Treatment: Relieved in two weeks by cleanliness, leeches to the temples, cold compresses, cocaine and atropine solutions, and nitrate of silver locally. August 6th, leucoma now disappearing under calomel insufflations and Pagenstecher ointment.

CASE II.—July 13th, M. J——, colored female, aged ten. Keratitis. History: In April a tea-leaf poultice was applied during two weeks for conjunctival irritation, with the result of producing intense redness of eye, which was relieved by cold. Present condition: Conjunctival congestion and keratitis. August 6th, improved.

CASE III.—July 16th, L. T——, white female, aged fifteen. Keratitis. History: In May a tea-leaf poultice was applied for conjunctivitis, which was aggravated by this treatment. Present condition: Conjunctival congestion and keratitis. August 6th, improved.

CASE IV.—July 23d; E. B——, female octoroon, aged five. Muco-purulent conjunctivitis. History: "Caught cold" in right eye about 10th of July, applied a tea-leaf poultice, which produced intense congestion and swelling of lids. Present condition: Chemosis of ocular conjunctiva, and congestion, with œdema of lids. August 1st, discharged, cured.

Other curious poultices are used on the eyes by the lower classes. Potatoes, yeast, liver, meat, and slippery elm are common materials. The two cases below are unusual.

CASE V.—June 3, 1887, M. P——, colored female, aged twenty-two, servant; pan-ophthalmitis. History: Applied at infirmary in April for keratitis of left eye, which was relieved in a few weeks, leaving a leucoma. The latter was gradually disappearing when she became dissatisfied, and, taking the advice of a friend, applied a poultice of lady-slipper flowers, the cypripedium arietinum. She stayed away from the infirmary for ten days, and returned in great anxiety with pan-ophthalmitis and threatening rupture of the cornea. The patient was treated at her home, but in vain, as the cornea soon sloughed and sight was irretrievably lost. When seen several months afterward the eyeball was atrophied.

There were no sympathetic symptoms in the right eye and no history of gonorrhœa.

CASE VI.—July, 1886, L. B——, male mulatto, aged forty, laborer in ice-house. Pan-ophthalmitis. History: Contracted a general cold which settled in his eyes. He then applied poultices (for two weeks) of the leaves of the jimson-weed, the datura stramonium. An attack of pan-ophthalmitis, in which the sight was lost, was the result. When seen about a year later both eyeballs were atrophied.

These cases exhibit some of the dangers from poultices applied to the eye by unskilled hands.

August 10, 1888.

ERYSIPELAS OF THE LARYNX—INTUBATION—LARYNGOTOMY.

By T. D. MERRIGAN, M.D.,

DEMONSTRATOR OF ANATOMY, MEDICAL DEPARTMENT, UNIVERSITY OF THE CITY OF NEW YORK.

ERYSIPELAS of the larynx is an infrequent occurrence. This is evidenced by the meagreness with which works on laryngology refer to it, and by the scarcity in the number of recorded cases. Mackenzie, in the latest edition of his book, cites four cases. Vol. xxxi., No. 17, of THE MEDICAL RECORD, contains an article by Dr. Delavan, entitled "Erysipelas of the Upper Air-passages," in which a case is described. Vol. xxxii., No. 11, contains the substance of a paper by F. Massei, of Naples, on "Primary Erysipelas of the Larynx." The paper was read at the last International Congress. Dr. Stockton, of Chicago, in discussing the paper, mentioned a case in which he had performed intubation of the larynx with a successful result.

This affection generally occurs by an extension of the morbid process from the exterior to the larynx, by way of the mucous membrane lining the nares and buccal cavity.

Rarely, it primarily attacks the interior of the larynx and thence extends from within outward.

The following case occurred in Charity Hospital: Nicola ——, aged thirty-three, Italian, laborer. On admission (May 17, 1888), was wildly delirious; temperature, 104° F.; pulse, 130, and respirations, 38 per minute. (No previous history could be obtained.) The face and scalp were enormously swollen, so that the features were unrecognizable.

Cloths wet with a hot solution of corrosive sublimate (1 to 2,000) were applied, and renewed as soon as they were getting cold. A gr. xv. dose of antipyrin was administered; tr. ferri chlor., ℳ xx., quinin. sulph., gr. v., t.i.d., and free stimulation with brandy were also employed. Under this treatment the patient rapidly improved.

On May 31st several collections of pus which had formed in the scalp and back were evacuated. From this time on the patient seemed to get better, the incisions healing by granulation.

The patient remained in the ward assisting the orderly, and frequently renewing the hot applications with which other patients, sick with erysipelas, were being treated.

July 14th, over a month after the erysipelas had disappeared from his face and scalp, he began to complain of some discomfort and difficulty in swallowing. There was a slight change in the voice at this time; it became hoarse and harder in quality.

These symptoms, at the time, were not deemed of any importance, and a gargle of potassium chlorate was ordered. The next day the patient was not any better; the dysphagia and hoarseness had increased; pain over the larynx was complained of; the glands at the angle of the jaw were enlarged; there was a throbbing headache; flushed face; increased temperature and rapid pulse. Flaxseed poultices were applied to the outside of the larynx.

July 16th.—The parts over the thyroid cartilage had become swollen and very tender. The pharynx was normal in appearance.

Laryngoscopic examination.—The epiglottis was very much swollen, intensely congested, and immovable; there was considerable tumefaction at its base; the ary-epiglottic folds were swollen, of a dark-red color, and almost closed the opening of the glottis; the vocal cords could not be seen. But a momentary glimpse of the larynx could be obtained at each insertion of the mirror, on account of the restlessness of the patient from the intense agony he was suffering.

A loud, high-pitched whistling note was heard at every inspiration. Expiration was not as difficult. A hoarse, croupy cough was present, which brought up from the larynx a thick tenacious mucus. A severe pain was felt in the epigastrium. The dyspnœa increased. Terror was depicted on the countenance; face livid and bathed with a cold sweat; eyes prominent, watery, and bloodshot; the extremities were cold; the voice had sunk to a whisper; the pulse was feeble, rapid, and small. An O'Dwyer tube was introduced, and this was followed by violent coughing and discharge of glairy mucus. Vomiting occurred in a few minutes and the tube was expelled. It was immediately reinserted, and this time it was retained. The breathing became easier, but still there were violent attempts at coughing. The patient was in an almost exhausted condition. Magendie's solution of morphia, ♏x., and brandy were administered hypodermically, and bottles of hot water applied to the extremities. The tube was retained all night. The patient slept some, but had occasional paroxysms of coughing. The next morning, during a fit of coughing, the tube was expelled.

Breathing was improved in the absence of the tube, and for that reason it was not replaced. The throat was sprayed with liq. ferri sulph. (gr. xvi.–℥ j.). The apparent improvement was only temporary. At 4 P.M. I was called hurriedly, and found the patient in a condition similar to that of the day previous. The pulse was 130, feeble and small. The O'Dwyer tube was introduced, but could not be placed so as to be retained. The ary-epiglottic folds had swollen enormously, preventing the tube from taking a proper position, so that as soon as the finger was removed from its head it came up.

It was introduced a number of times, but as often rejected. The patient was quickly growing worse. During inspiration there was marked retraction of the supra- and infra-clavicular and the supra-sternal regions, the epigastrium, and the lower ribs. The respiratory murmur was scarcely audible behind between the scapulæ. The face was becoming purple. He was throwing himself about in a frenzy in his efforts to obtain breath.

Refusing to allow further attempts at introducing the tube, and as suffocation was imminent, laryngotomy was decided on as a *dernier ressort.* The temperature was 100° (in the axilla), pulse 140, feeble and irregular. ♏xv. of a four per cent. solution of cocaine was injected along the median line for three-fourths of an inch above and below the cricoid cartilage. Local anæsthesia was perfect, and the usual steps of the operation were gone through without any pain. Hemorrhage was inconsiderable, and readily controlled by compresses wrung out of hot water. The crico-thyroid membrane was opened and the tube introduced. The introduction of the tube was followed by a severe fit of coughing, and a large quantity of mucus was expelled. All the unfavorable symptoms rapidly subsided, the cyanosis quickly disappeared, and the breathing became easier.

Magendie's solution, ♏x., and brandy were given hypodermically, and a steam spray was directed across the opening of the tube. One hour after the operation the pulse had grown stronger and was 102 per minute.

July 18th.—The patient slept a good deal during the night, but was frequently awakened by the cough. Tr. ferri chlor., ♏xxx., with glycerine four times a day. Tr. belladonnæ, ♏x., was given, with the effect of diminishing the amount of secretion and quieting the spasmodic cough. Examination of the larynx showed an increase of the swelling; the opening of the glottis was but a chink; the ary-epiglottic folds had a dark-red angry-looking appearance; the epiglottis was swollen, stiffened, and curved upon itself; there was very slight redness of the pharynx, tonsils, and uvula. Temperature, 99.8; pulse fairly strong and regular, 84 per minute. A slight red blush had appeared at the lower part of the wound. Urine, sp. gr., 1.018, no albumen or casts, reaction acid; heart and lungs negative; bowels regular.

July 20th.—The edges of the wound had become swollen, dry, and red; the redness extended for about an inch on either side. This was controlled and caused to disappear by painting the edges with tr. iodinii. From August 2d the general condition gradually improved, the patient remaining out of bed during the entire day, taking nourishment and seeming well but for the condition of the larynx. The spray was discontinued, July 28th, owing to the retching it occasioned whenever it was used. Potassium iodid., gr. xv., t.i.d., was given with a view of absorbing the exudation. The larynx showed no sign of resolution. The granulations on the surface of the tracheal wound grew large. An exceedingly fetid pus was discharged from the trachea every time the tube was removed. Breathing through the larynx without the tube was tried a number of times. On some occasions breathing could be carried on for a short time, but at others he was unable to breathe at all. The voice lost some of its hoarseness, but never became normal. Frequent laryngoscopic examination showed not the slightest diminution in the thickening of the epiglottis and ary-epiglottic folds. Occasionally severe dyspnœa would occur from the plugging of the tube with mucus, but this would disappear when the tube was cleaned. The temperature ranged from normal to 100.4°; the pulse varied from 72 to 96 per minute. When dyspnœa would occur, it would increase in rapidity; respirations, 20 per minute.

On August 15th, while the inner tube was being cleaned by the orderly in charge of the case, the patient, suddenly and without any warning, frantically seized hold of the outer tube, tore it from its place in the larynx, threw it across the ward, fell back, and before a physician could be summoned the patient was dead. He was feeling very well previous to this sudden termination.

Autopsy.—The thoracic and abdominal organs were normal, except for a few old pleuritic adhesions. The parenchyma of the lungs were in a healthy state. The edges of the wound and the soft parts about it in the interior of the trachea were in a sloughing condition. The cricoid cartilage was in a state of necrosis, very much thinned, especially its anterior portion; it was freely movable and completely detached from all the soft parts, which formed a cylindrical shell about it. There was a large amount of exudation into, and thickening of, the epiglottis, its base, and ary-epiglottic folds. The latter were in accurate apposition, acting as a valve and completely closing the glottis to the entrance of air.

SWEATING OF THE FEET.—Dr. Legoux uses a mixture of glycerine two and one-half drachms, solution of perchloride of iron one ounce, and essence of bergamot twenty drops, in the treatment of bromidrosis of the feet. The feet are bathed frequently in cold water for two days, and, on the third day, are painted with this mixture. The painful sense of heat gives way to a feeling of refreshing coolness, the moisture becomes less apparent, and with it disappears also the disagreeable odor. The applications are to be continued night and morning. The author obtained by this means the cure of a case, which had resisted all other treatment, in two weeks.—*Gazette Médical de Picardie.*

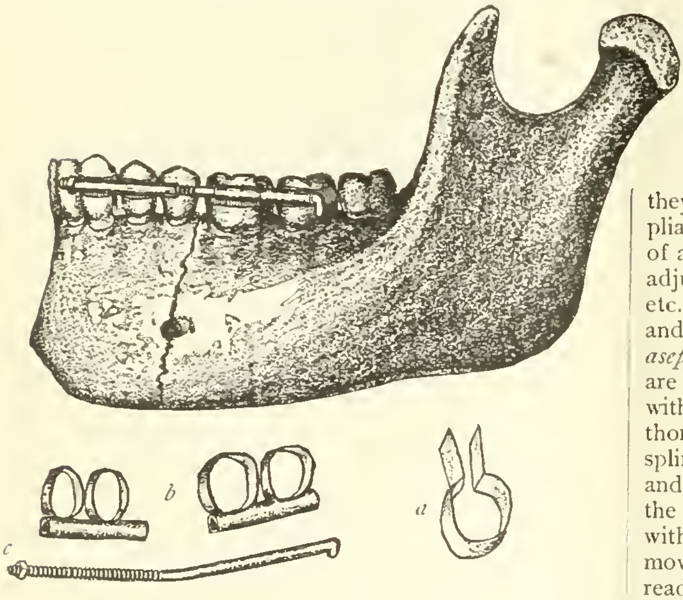
FURROWS ON THE FINGER-NAILS.—Dr. E. G. Roberts, of Fair Haven, Vt., writes: "The brief notices in THE MEDICAL RECORD on the above subject have greatly interested me, as they recall a similar condition in my own case some years ago. In May, 1876, when a student, I suffered from a severe attack of varioloid, and when convalescing I noticed a very marked transverse furrow on all my finger-nails, which remained until that portion of the nails grew out. I do not remember whether the toenails were similarly affected or not, but shall be more observant in the future."

AN ANCHOR-SPLINT FOR FRACTURE OF THE JAW.

By CHARLES G. BROWN, M.D.,

MINNEAPOLIS, MINN.

It has been my misfortune to have to treat three cases of fracture of the jaw, and my privilege to assist in the treatment of several others. Not until one has such a case does he fully appreciate the difficulties to be encountered and the inefficiency of the methods spoken of in our text-books. In the treatment of fractures in all localities our success is in direct ratio to our recognition and antagonization of the physiological contraction of muscles, restoring the lost balance of action and thereby securing rest in proper position. In fracture of the femur the contractions approximate the ends of bone, and by the pressure cause absorption, or if the fracture is oblique, sliding by of the ends, in either case resulting in shortening of the bone; while in fracture of the patella the fragments are separated so effectually that seldom, if ever, anything more than ligamentous union results; not because the structure of the bone is different, but because of the difficulty in securing anchorage sufficient to resist the contractions of the extensor muscles.



When we consider the great range of occlusion of the jaw, we can appreciate the variety of displacements which may occur in fractures of this bone; the muscular movements are complex and delicate, none being very strong except the masseters on either side. The broken fragments can, as a rule, be reduced and held in position with but little force, if it be applied in the *right direction*. By taking a skull in the hand, and drawing a line from the symphysis to the centre of either condyle, it will be seen to represent the *resultant* of all the normal forces to which the corresponding half of the jaw is subjected. Now, if we apply the usual bandage it will be seen to cross this *resultant force line* at an *acute* angle, whereas, to be effectual, it should cross it at a *right* angle, which would bring the opposing point in front of the nose instead of the top of the head. It is my purpose, in this brief paper, to call attention to a principle which it is believed will be efficient in maintaining the proper force in the proper direction.

My friend, Edward H. Angle, D.D.S., of Minneapolis, has perfected a system of appliances for correcting irregularities of the teeth, consisting of metallic bands, pipes, screws, springs, etc., applied to the teeth in such a way as to be neat and efficient. (See Haskell's "Compendium," and Guilford's "Orthodontia," now in press.) It is proposed to utilize a portion of his system, that of anchorage, in retaining fractures of the jaw. The principle will be more readily understood by reference to the accompanying illustration.

Two or more firm teeth are selected on either side of the fracture, and carefully banded with German silver made into a loop and slipped over the teeth; the band is grasped with flat-nosed pliers and drawn snugly about the teeth; a burnisher will be of assistance in getting a close fit; the band is now removed and presents the appearance shown at *a*. The ends are now clipped off and soldered. The bands are again slipped over the teeth and a piece of hollow tubing or joint wire one-half or three-fourths of an inch in length, one on each side of the line of fracture, is placed against the bands and marked at point of contact. The bands are again removed and the pipes soldered to them as shown at *b*. A traction screw made of *hard-drawn* German silver, and shown at *c*, is passed through the tubes and the nut started. A rubber dam is next applied to the teeth to keep them thoroughly dry, and the appliance slipped over the teeth and cemented in place by oxyphosphate of zinc. After it has thoroughly set, the nut is tightened until the ends of the bone are brought into place; additional strength may be acquired by attaching a similar rod on the lingual side. The whole being immovably cemented to the teeth (if properly done), it will readily be seen that the force is applied from the full length of the teeth, which prevents their tipping, and a firm anchorage is secured by means of which the fragments of the broken bone are held immovably in position—a *Malgaigne splint*, if you please, except that the *hooks* are not foreign bodies. The teeth do not tip and loosen as when they are simply wired together at the top. The appliance can be made and adjusted with the assistance of any competent dentist, and does not require frequent adjustment as where the interdental splint or bandages, etc., are used, and which are so annoying to the patient and monotonous to the surgeon. Last, but not least, it is *aseptic*. Owing to the closely adhering gums these fractures are usually compound, and the discharge of pus mixed with increased flow of saliva, food, etc.—which cannot be thoroughly and frequently removed when the interdental splint is used—the mouth becomes a hot-bed for bacteria and foul odors; to this is frequently added sloughing of the skin under the jaw from bandage pressure. While with the anchor-splint this is avoided, the patient can move the jaw, keep his mouth clean, take food more readily, and free from sepsis; thereby better maintaining his health, and finally securing better occlusion of the teeth than by the methods commonly practised.

Congenital Absence of both Eyes.—Dr. Menacho recently described the case of a little girl, of thirteen months, the subject of double anophthalmia. The eyelids, lachrymal apparatus, and orbits appeared to be well formed, but there was no eye on either side, a simple cavity being seen on separating the lids. This cavity was invested by the conjunctiva, which apparently rested on some firm fibrous basis, in which movements could be detected as if they were rudiments of the ocular muscles. In the thickness of both inferior eyelids a kind of bursa or cyst could be felt, that on the left side being the larger, and having a whitish coat like the sclerotic, which could be seen through the conjunctiva posteriorly, where it was thin and transparent. This became tense during crying, and the child was observed to press it frequently with her hands and then to smile, a phosphene or subjective sensation of light being probably thus produced.

Hot Water in the Treatment of Carbuncles.—Dr. J. C. Abernethy recommends the use of compresses dipped in boiling water for the cure of carbuncles (*The Medical Age*, June 11, 1888). He first employed it when he was himself suffering from a carbuncle, and found that it not only relieved the pain almost instantly, but promoted a rapid cure.

COCAINE CONJUNCTIVITIS.

By CHARLES J. KIPP, M.D.,

NEWARK, N. J.

While it is well known that the long-continued use of alkaloids like atropine, duboisine, and eserine occasionally produces inflammation of the conjunctiva and swelling of the conjunctival follicles, the fact that cocaine sometimes, though rarely, causes a similar conjunctivitis, has not, so far as I know, been brought to the notice of the profession. Since the introduction of cocaine into ophthalmic practice I have used this drug alone, or in combination with other alkaloids, in very many cases, and sometimes continuously for many weeks, for various affections of the eye. Up to six months ago I had never seen a case in which a conjunctivitis followed the use of this drug; but since then I have had three cases of follicular conjunctivitis clearly attributable to its use. For my present purpose it seems unnecessary to give a detailed description of the diseases for which the cocaine was prescribed, and I shall therefore content myself with the statement that in one case it was given for the purpose of allaying the irritation due to spasmodic entropion, in one for an ulcer of the cornea, and in the other for an irritable condition of the conjunctiva resulting from exophthalmus. The last case I reported at the last meeting of the American Ophthalmological Society, and the occurrence of the cocaine conjunctivitis was mentioned only incidentally. The patients were all over seventy years of age, and had no conjunctivitis before the cocaine was used. In all, the use of the drug had been continued, without my knowledge, for a period varying from two to four months. All used a simple solution of cocaine, ten grains to the ounce of distilled water. The drug used by these people was obtained from reliable apothecaries of different towns and produced no marked irritation when first instilled. How soon after the commencement of the instillation the conjunctivitis appeared I am unable to state, as I had not seen the patient for many weeks at the time I discovered the presence of the conjunctivitis.

The picture presented was essentially the same in all the cases. Burning and itching of the eyes and moderate dread of light were the symptoms chiefly complained of. The lids were somewhat puffy but not red, and slightly excoriated at the corners. There was considerable secretion of the thin viscid fluid, not unlike the mucilage from the conjunctival sac. Purulent secretion was not noticed in either of the cases. The ocular conjunctiva was slightly œdematous and of a dirty yellowish color. Greater changes were seen in the palpebral conjunctiva. This was swollen and of a reddish-yellow color throughout, and its surface was closely studded all over with translucent elevations (follicles), mainly of the size of sago-grains. The follicles were perhaps most numerous on the swollen retrotarsal folds. The condition of the palpebral conjunctiva was indeed very much like that caused occasionally by the long-continued use of atropine, except in this that the color of the conjunctiva was yellowish red instead of bright red. The swelling of the retrotarsal folds was the same. In all the cases the upper and the lower lids were affected alike, and both eyes presented the same appearance. I discontinued the application of the cocaine solution at once, and ordered instillation of a half per cent. solution of sulphate of zinc twice daily, and under this treatment the follicles disappeared in the course of six weeks. All signs of conjunctivitis had disappeared when I last saw the patient.

Catha Edulis is the name of a plant found in Eastern Africa from Abyssinia to Port Natal. It possesses stimulating properties similar to those of coffee, but apparently more pronounced. It does not, however, contain any caffeine, according to Flückiger, but another alkaloid to which he has given the name of katine. The Mohammedans are said to chew the leaves, the juice of which produces a wild sort of intoxication.—*Der Fortschritt.*

Clinical Department.

A CASE OF PNEUMONIA WITH DELAYED RESOLUTION — ABSCESS OPENING EXTERNALLY—RECOVERY.

By BENJAMIN EDSON, M.D.,

BROOKLYN, N. Y.

While cases similar to the following do sometimes occur, they are perhaps sufficiently rare to warrant their being reported and made a matter of record.

Gertrude H——, aged eight; a strong, fat, and healthy child, was attacked with pneumonia about May 20, 1886. The treatment during the first five weeks was said to have been vigorous and varied—just what I do not know, nor is it material to this report of the case. I first saw her, June 25th, following. She was then reduced to a mere skeleton. For nearly three weeks she had lain upon the right side, in a half-reclining position, with the head bent forward and the knees drawn up to the abdomen. Transversely across the anterior aspect of the legs just above the knees, as the result of the long and severe tension, were a number of wide, white lines, not unlike *linea albicantes.* There was a harassing, partly suppressed cough, with but scanty expectoration of frothy mucus and a little thick, yellow sputa.

Examination revealed consolidation of the lower and middle lobes and the anterior portion of the upper lobe of the right lung, with, as a matter of course, exaggerated respiration on the left side. By direction of the attending physician the surface of the chest over the *left* lung had been repeatedly painted with tincture of iodine until it was so raw as to render examination difficult and distressing. To all appearance the child was rapidly sinking, and the prognosis was most unpromising. Attention was given to modifying the irritating cough, and especially to stimulating the appetite and sustaining the strength of the patient. The subsequent course of the disease may be traced by the following extracts from notes of the case.

June 29th.—Temperature, 102½° F.; pulse, 150; respiration, 46. Passing but little urine; traces of albumin; feet greatly swollen; solution of potass. bitart. to be used freely as a drink.

July 2d.—Temperature, 102° F.; pulse, 150; respiration labored and variable; drowsy; kidneys have acted but once and slightly in twenty-four hours; face, abdomen, and legs swollen to their fullest tension; great depression.

July 4th.—Slight improvement; kidneys doing a little better, but their action is far from satisfactory. The child is taking some food with a relish.

July 5th.—Projecting between the first and second ribs, three-fourths of an inch to the right of the sternum, is an abscess about the size of a hickory-nut. Its walls are thick and firm, expanding and contracting somewhat at each inspiration and expiration. It is deemed best not to disturb the abscess, for the present at least. The patient eats ravenously. The diet embraces steak and potatoes, bread and butter, clam fritters, mince pie, bananas, oranges; in fact, nothing edible seems to come amiss, and no restraint is exercised in regard to either kind or quantity of food taken.

July 8th.—Is still eating well, double the quantity of an ordinary laboring man. Coughs considerably. Temperature still high.

July 10th.—Another abscess, larger than the other, has appeared one and a half inch below the right nipple. The wall is red, thin, elastic, distending much at each inspiration. Evidently rupture must soon occur. It was decided, however, not to open the abcess at present.

July 11th, 6 A.M.—Lower abscess opened spontaneously, discharging, as estimated, between one and two pints of pus. Whenever the child coughed the matter spurted in a stream to a considerable distance. When the bulk of it had been discharged, the air at each respiration passed freely through the opening into the cavity, and through a communicating bronchus and the trachea. The adhesions of the chest-walls and pleura were complete, no pus escaping internally. The upper abscess disappeared. For some hours the child was almost in collapse. At this point, and here only, stimulants were freely given. Later in the day she began to rally, and the ravenous appetite was again demanding supplies for the exhausted system. Absorbent cotton soaked in listerine was placed over the opening and renewed from time to time as found advisable.

July 13th.—Temperature, 101° F.; pulse, 138; respiration, 40. Cough has entirely ceased; abscess still discharging abundantly; free passage of air through the opening. The character of the discharge is so satisfactory that it is not deemed advisable to attempt to wash out the cavity with an antiseptic solution. General condition slightly improved.

July 18th.—Temperature approaching normal; abscess still discharging freely; kidneys acting properly; dropsy has disappeared; gaining strength.

July 28th.—Is up and out in the yard; discharge about two ounces in twenty-four hours; air still passing through the opening.

August 16th.—Improving rapidly; discharge but nominal; very marked sinking in of the chest on the right side, and lateral curvature of spine; she has the appearance of a hunchback. Began the practice of moderately deep inspirations several times a day, with the hope that enough sound lung-tissue remained to eventually fill the chest and overcome the deformity.

November 20th.—Is substantially well. Spine nearly straight, and chest filling out satisfactorily. Attendance discontinued. Recovery may be considered complete.

At the present time she is strong, hardy, and active, and there is little to indicate the serious ordeal through which she passed. Very little medicine was given, and it seems as though she actually *ate* her way through. It is not quite certain that even the stimulant that was given in the critical period might not have been dispensed with without serious detriment. Had the abscess been opened even but a few hours before the time it actually did break, the operator would naturally have taken to himself credit for contributing to the favorable result.

From the advocates of antiseptic treatment may come the criticism that without it the patient was exposed to serious risk. In that respect these notes of the case may be misleading, for a study of the *patient* from day to day and hour to hour led me to the most conservative policy; and I am satisfied to accept the result as vindicating the methods pursued.

A good constitution, generous diet, and active digestion, with symptomatic treatment, accomplished all that could have been attained by the most rigorous and active measures.

A CASE OF ACQUIRED ATROPHIA UTERI.

By C. M. HANSEN, M.D.,

CROOKSTON, MINN.

It is a well-established fact that an atrophy of the uterus can develop after parturition, not only following a severe puerperal sickness or caused by tuberculosis, but also after a completely normal childbirth or abortion. In these cases the atrophy develops gradually, almost without symptoms, during or shortly after the confinement, but is later accompanied by different nervous troubles, abdominal pains, psychic depression, and hysteria. The menses cease and the uterus and ovaries are found in various degrees of atrophy.

I wish to refer to these more common cases of puerperal atrophy before I report the following case that has had quite a different course.

On April 1, 1888, I was called to a young girl who had suffered from incessant vomiting for more than two months, in spite of regular medical treatment. I found her apparently moribund, and emaciated to such a degree that a nine-year-old boy, who was present, could make his fingers of one hand meet round her thigh just above the knee. She had bed-sores on the hips and os sacrum and scorbutic spots on the chest and the legs. She was fully conscious, had no pains except headache, but she was extremely weak and was absolutely unable to retain any nourishment, and had hardly been able to retain any for about two months. The excretions had in the last days been passed involuntarily. Temperature, 97.5° F.; pulse rapid and very weak. In the urine a few clear casts, no albumen nor sugar. The lungs were normal; the heart-beat was in the right place, the first sound being accompanied by a strong anæmic murmur. The abdomen was deeply depressed and the spine very prominent in front; in the right epigastric region the abdominal aorta presented itself like a pulsating tumor. The anæmic murmur was very pronounced over this part, so that at first sight it simulated an abdominal aneurism. No thorough examination of the generative organs was made, only enough to exclude the possibility of pregnancy. I tried at once the stomach-tube, and succeeded in giving her a little buttermilk and whiskey, which she retained without vomiting afterward. As this strengthened my suspicion that her disease, however severe, was of functional origin, I applied the faradic current, as strong as she could stand it, in the cardiac and epigastric regions of the abdomen, and ordered the electricity to be applied three times daily for about ten minutes each time.

The patient, Sigrid M——, aged twenty-one, came from Norway to Minnesota in the spring of 1887, and was engaged as girl in a hotel. She was of healthy parentage, robust, and had never been sick. Her menses had always been regular, without any pain. In the fall of 1887 she passed two of her periods, and went therefore to a Frenchwoman, who produced an abortion. The abortion was accompanied by a severe hemorrhage, and she was confined to her bed for about fourteen days, but had no fever. After her sickness she obtained an easier place, where she could not possibly overwork herself. *She was perfectly healthy at that time*, only a little weak, and her digestive functions were in good order. But the menstruation did not reappear, and she has never had any sign of them since. In the latter part of January she began to feel sick, and had headache and vomiting, worse in the morning. The vomiting increased in vehemence and did not yield to any diet or medicine. She was confined to bed during the two following months with incessant vomiting, till she had reached the condition wherein I found her, April 1st. She was nursed in a quite comfortable house and had her own brother to attend to her.

Against all expectations she began to recover from that day; the next day she could take buttermilk without the stomach-tube, and was able to retain this and other light food. She then began to gain flesh, and the scorbutic spots disappeared. That there was no local disease of the stomach is evident, as one week after my first visit she could enjoy beefsteak with pickles and coffee. On May 1st she could stay out of bed the whole day. She still suffered occasionally from headache and was subject to slight hysterical fits, but these too have now—in the last days of July—quite disappeared, and she is in a good way to regain her former health, being fully able to work. Her courses have never returned. Of medicines she has only used whiskey and tinct. ferri. muriat.; the electricity was disposed of as soon as I was sure of her improvement. The anæmic murmur has disappeared, the sounds of the heart are clear, and the abdomen is natural.

The recto-vaginal examination shows a complete atrophy of the corpus uteri. The portio vaginalis is of about natural shape and size, and it is continued upward into a narrow, spool-shaped body, that can be traced out to the left side of the broad ligament. A real fundus uteri cannot be felt. The ovaries are felt as small bodies in normal places. There are nowhere any traces of inflammation, and the bimanual examination was made without any pain. The edge of the os uteri is soft and slightly curved in on the left side, possibly caused by the abortion.

The first impulse in this uncommon case would be to diagnose the sickness—that could only be considered as functional—as an excessive anæmia, caused by the hemorrhage of the abortion, the consequent atrophy of the womb being caused by the anæmia. Against this I must state that she was quite healthy for about a month after she recovered from the abortion, and even then the symptoms of her sickness gradually appeared.

My view of this case is that the atrophy of the corpus uteri developed as a direct consequence of the puerperal involution of the uterus, on the same anatomical basis as in the more common puerperal atrophies, to which I referred above, but with unusual rapidity, and accompanied by very exaggerated nervous symptoms. If my view be right, we have in this case, both as to origin and course of the disease, an interesting analogue to a serious case of vomiting during the first months of pregnancy, the same nervous phenomena being produced by the rapidly decreasing as by the rapidly increasing uterus.

Whether the treatment had any effect, or whether I just came to the patient at the moment that the degeneration had terminated, I cannot say. I did not make any thorough examination of the generative organs before she had got nearly well and had recovered from the state of nervous excitement in which she was during the first time of her convalescence. It is my wish to draw the attention and the criticism of the members of the medical fraternity to this case, and would be glad to hear the opinions of others regarding it, as I have been unable to find any similar case reported in the works I have at my disposal.

A CASE OF UNCOMPLICATED DISLOCATION OF THE CARPAL SCAPHOID BONE.

By NOLAN STEWART, M.D.,
BURDETT, MISS.

On the night of May 27, 1888, N. A. H——, white, male, aged twenty-four, called to see me to have his left wrist examined.

He furnished this history: He was driving through a large grove that night in a gig, a companion being with him. The road was quite rough, the soil being of the variety known here as "buckshot." It is low, and when wet is very sticky and tenacious. Vehicles passing over the road in that condition leave many sharp projecting clods, which dry and become as hard as a brick. The horse was trotting at a gait somewhat faster than the average, when one of the two wheels struck a stump, overturning the gig and throwing out the two occupants.

The man's wrist was very much swollen, but I could detect a tumor upon the dorsal surface.

I satisfied myself that there was no fracture of any bone in that vicinity, and concluded that the tumor was due to a dislocation of one of the carpal bones. The deformity, as before stated, was discernible, though largely concealed by the swelling.

I noticed an abrasion of the integument upon the anterior surface where it had struck upon one of the sharp masses of earth. The body fell upon this hand. The parts being so much swollen, and knowing a simple dislocation of this bone, the scaphoid, to be very rare, I directed the employment of active antiphlogistic measures until morning, when I could satisfy myself of the correctness or incorrectness of my diagnosis, viz., luxation of the carpal scaphoid. I saw my patient at my office next morning, when I found that the swelling was greatly reduced, and so was enabled to make a satisfactory examination of the parts. I then confirmed my diagnosis. I could easily define the outline of the scaphoid bone, and the deformity resulting from its dislocation was well displayed now that the swelling was reduced.

The signs of luxation were present, deformity, preternatural immobility, and ability of the parts to maintain their normal position when brought into place, as was afterward shown.

I made traction upon the hand, at the same time carrying it as far as possible to the ulnar side. I then made firm pressure upon the tumor, when to my satisfaction the scaphoid resumed its proper position. I applied an appropriate dressing. The parts remained tender for quite a while, but at this time the functions of the wrist are well performed and no protracted inconvenience has resulted from this unusual form of dislocation.

BALSAM OF PERU AS A SURGICAL DRESSING.

Dr. A. H. Rockwell, of Mancelona, Mich., writes: "About three years ago I read an article in some medical journal (which I am unable to find) on balsam of Peru as a surgical dressing, in which the author claimed that he had obtained very flattering results, the wounds healing kindly and without suppuration. The cases in which it was used were those involving solution of surface continuity from injury. Since reading the article I have used balsam of Peru in a number of cases, mainly cases of fingers and hands, cut and bruised in our saw-mills and factories. I have amputated fingers, sewed up cuts and lacerations, dressed mangled and bruised fingers and hands, and have used balsam of Peru as a dressing, and they have healed quickly, with very little suppuration or inflammatory action, and in many cases almost absolutely without either. In cases where the tissues are bruised and mangled, where we would expect a good deal of sloughing, the tissues, instead, become dried and hard, and, after the wound has healed, separate and become detached in much the same way that a scab separates from the surface of a wound that has healed beneath it. I have also noticed that the balsam has a hæmostatic effect, being quite an effectual agent. I have watched the progress of wounds with this dressing, which is applied on lint or cotton, and it seems to me that the process of healing more nearly approximates nature's method. *i.e.*, healing under a scab, than with any dressing with which I am acquainted. The advantages which may be claimed for it are, it furnishes perfect protection (it practically seals the wound), is clean, has a pleasant odor, does not require to be frequently renewed, for there is almost entire freedom from suppuration, and the results in my hands have been uniformly and eminently satisfactory."

China Grass as a Wound-dressing.—Mr. H. B. Hewitson, in *The Lancet*, adds another to the long list of materials for surgical dressing. He says: "China grass is a soft, silky, very highly absorbent fibre, used in various manufactures. The combings form an elastic silken wool which, when treated with four per cent. of salicylic acid, provides an excellent antiseptic absorbent surgical dressing. It is also relatively much cheaper than, so far as I know, any of the usual dressings used in surgery. I have now given it an extended trial, and supported by the opinions of most of my medical friends. Its chief value is the way in which it absorbs discharges from a wound, rendering it very dry, and preventing the poulticing of the wound, as it were, when bathed in discharges under less absorbent materials. A considerable quantity is required in cases where the discharges are free, and it is perhaps well to interpose some open-meshed gauze between the dressing and the wound, so as to prevent the China grass from sticking to the wound when removed. I have also observed that under the pressure of bandaging the material still retains its absorbent qualities, and does not cake when properly teased out before use."

Progress of Medical Science.

The Uselessness of the Hypodermic Employment of Iron.—The Paris correspondent of *The British Medical Journal* writes that M. Hirschfeld has lately discussed the question of the hypodermic injection of ferruginous compounds, in a thesis for the Doctor's degree. After a short review of the various works which have appeared on this subject since 1872, when Professor Rosenthal, of Vienna, first employed iron preparations in hypodermic injections, the author proceeds to describe his own experiments at the Hôpital Cochin. His observations have led him to conclude that the method of administering iron preparations by means of hypodermic injections is excessively painful to the patient, and inefficient in its result. In defending the system of administering iron compounds internally, M. Hirschfeld quotes the opinion of Professor Hayem, who states that he has hardly ever met with a patient who could not take iron salts.

Tubercular Disease of the Ear.—Dr. Habermann recently made a communication on tubercular disease of the ear to the Verein Deutscher Aerzte of Prague. He had seen eighteen patients affected with tuberculosis who suffered from hardness of hearing and otorrhœa. In nine of these cases he detected the presence of tuberculosis of the auditory apparatus; in seven, purulent otitis media; and in two catarrhal swelling of the mucous membrane of the middle ear was present. He described two of these cases in detail. In a child, aged one and a half, there was tuberculosis of the mucous membrane of the middle ear, beginning at the isthmus tubæ and reaching as far as the antrum mastoideum. There was no perforation of the membrana tympani. This case was remarkable on account of the localization of the affection. Various parts of the mucous membrane of the middle ear were found to be affected with tuberculosis, and evidence was thus given of the spread of the disease in the middle ear by infection from contact. The possibility of infection of the ear taking place through the Eustachian tube was, by such observations, rendered more probable. By way of illustrating infection by contact in such cases, Dr. Habermann showed the membrana tympani of a man, aged thirty-one, which presented a large perforation at the anterior part, and three small perforations at the posterior one; the latter were due to the fact that the membrana tympani was attached at that point to the mucous membrane of the promontory, which was affected with advanced tuberculosis. The second case which he described particularly referred to the condition of the internal ear, as the middle ear had already been completely destroyed by caries. The disease, in this case, had supervened in the middle ear, a year and a half before the patient's death; later on it gave rise to perforation of the wall of the labyrinth, and to extension of the disease into the internal ear. Proof of this was afforded by the fact that the morbid process in the internal ear had already, in part, undergone retrogressive metamorphosis, when the progressing carious process of the bone led to a new affection and destruction of the structures of the internal ear.—*The British Medical Journal.*

Tympanites Treated by Puncture.—At a meeting of the Hunterian Society (*The Lancet*), Dr. R. J. Ryle read a paper on a case of tympanites treated by puncture through the abdominal wall. The patient, a man aged forty-six, came under treatment in October, 1887, with vomiting, paroxysmal pain, and constipation of about ten days' duration. Examination of the abdomen showed considerable fulness, but no tumor was felt, and examination per rectum revealed nothing. Enemata and O'Beirne's tube gave no information. Colotomy was proposed, but declined by the patient; therefore puncture of the intestine to relieve distention was resorted to as the only treatment which promised relief. Eight punctures were made, with considerable relief to the distention, but with the result of setting up an attack of violent preistaltic contraction about half an hour afterward. Three days later it was necessary to puncture again in three places, and two precautions were used to prevent peristalsis—viz.: (1) Hypodermic injection of morpho-atropine, and (2) use of a larger aspirating needle. A very large quantity of gas was evacuated. No violent peristalsis followed. Forty-eight hours later the bowels opened. After a fortnight symptoms of obstruction returned, and puncture again became necessary, the same precautions being taken as on the former occasion, and in the course of the following three weeks puncturing was four times repeated. Great temporary relief was gained, but the patient gradually sank and died. A post-mortem examination showed an annular stricture of the first part of the rectum, but no evidence of peritonitis or extravasation of fæces, and, with the exception of certain small black spots, no trace of the puncture was visible in the wall of the bowel. The points of interest in the diagnosis of this case of chronic obstruction were then discussed, and secondly those of the treatment by puncture. As to the latter, the relief afforded by this procedure was of value, for three reasons: 1. As checking the respiratory and circulatory difficulties consequent on extreme distention. 2. As diminishing the direct risks of distention—viz., rupture and peritonitis. 3. As favoring the re-establishment of the normal intestinal action. The chief mode, however, in which puncture tended to produce evacuation of the bowel is by exciting brisk peristalsis, and this is a result which, as in the present instance, may require to be guarded against. As to the dangers of intestinal puncture, it is impossible to state that there are none; thinning or ulceration of some part of the bowel may convert a puncture into a rent. The same might happen from movement of the impaled bowel, or liquid fæces might be conveyed from the needle to the peritoneum. But a much less hypothetical danger seemed to be the rupture of the diseased bowel by the violent peristalsis set up by puncturing, or if the puncturing is very free. The reality of this risk is shown (possibly) by the history of a case of Dr. Bristowe's, recorded in the "Pathological Society Transactions" for 1872; and still more clearly by a case recorded in 1878 in the *British Medical Journal* by Dr. Coupland and Mr. Morris, in which rupture was due to peristalsis caused by puncture. If this view of the danger be correct, the proceeding comes to resemble the administration of ergot during labor, and the cases most suitable for the treatment would seem to be those characterized by healthy bowel and an absence of insuperable obstruction, such as sometimes occur in obstetric practice or after abdominal operations. Perhaps, too, as has been suggested by Dr. Galabin, this treatment might be of use in commencing peritonitis. The beneficial effects of simple relief of tension in checking the progress of inflammation are shown in periostitis and cellulitis, and probably a few needle punctures would be less dangerous than continued distention to the peritoneal coat. From similar considerations he suggested its employment in enteric fever, more especially if, as was probable, excessive peristalsis can be prevented by opium.

Syphilis and Cancer.—Professor Lang, of Vienna, read a paper recently on the "Coexistence of Syphilis and Cancer." But little attention had been hitherto directed to the fact that syphilis sometimes formed the predisposing soil for the development of cancer, or that both diseases might be combined with each other. Setting aside some observations of comparatively little value which had been made by ancient authors on the subject, it was especially Hutchinson and Langenbeck who, before Professor Lang, had directed attention to the simultaneous occurrence of syphilis and carcinoma. The speaker had observed such a combination four times. The first case was that of a patient who had been admitted in 1883 under his care when he was at Innsbruck. Besides an old-standing iritis and other symptoms of syphilis, he was suffering from serpiginous and gummatous ulcerations on the nose, the cheek, and the angles of the eye. Most of the ulcers healed under antisyphilitic treatment, except one, which gradually changed its character and assumed the form of an "ulcus rodens," that is, a flat carcinoma of the skin. The patient was transferred to the surgical clinic, where he underwent an operation, and microscopical examination proved the simultaneous existence of both syphilis and carcinoma. The second case was that of a patient, aged forty-six, who had previously been treated for recent syphilis by Professor Lang. There were syphilitic infiltrations of the floor of the mouth and under the tongue, and, moreover, various syphilitic infiltrations over the occipital bone and the body. All these lesions subsided under the influence of a common antisyphilitic treatment, except the infiltrations of the floor of the mouth, which became transformed into cancer. The third case was that of a man, aged about thirty, who presented a syphilitic ulcer on the under lip. The ulcer disappeared under antisyphilitic treatment, but relapse and transformation into carcinoma occurred a year later. In all these cases the correctness of the diagnosis was proved by the anatomical examination. The fourth case was shown to the Society. The patient had extensive scars, ulcerations as well as infiltrations on the forehead, loss of the entire nose, loss of substance on the upper lip, ulceration and perforation of the hard palate, perforation of the soft palate, and cicatricial retraction of uvula. On admission of the patient into the clinic of Professor Lang, in the middle of January last, some of the ulcerations were covered with a white tallowy mass, which led Professor Lang to suggest the presence of a combination of syphilis with carcinoma. The microscopical examination, however, revealed only the presence of pus corpuscles and products of decomposition. The infiltrations on the right side of the forehead later on slightly diminished, but from four to five weeks later a vegetation on the anterior end of the ulceration of the hard palate appeared, the character of which was incompatible with that of syphilitic ulceration. A part of this vegetation was excised, and the microscopical examination of it, which was made by Professor Weichselbaum, showed that it was "epithelial carcinoma."—*The British Medical Journal.*

Smoker's Vertigo.—At a meeting of the Académie de Médecine, M. Decaisne spoke on the vertigo of smokers. He said that numerous experiments have proved that nicotine contracts the muscular coat of the vessels, and that vertigo was due to the exaggerated contraction of the arteries of the brain. The patient experiences a feeling of emptiness in the head, so much so that he seems as if about to faint. Everything turns round, and his ideas become confused. M. Decaisne found that these phenomena were chiefly found in smokers above fifty, and especially in those who smoked habitually before meals. He had known several of these persons to be treated for cerebral congestion, and even disease of the heart, with the result, as might be supposed, of increasing the symptoms. The treatment consisted in absolute abstention from the weed, and some slight laxative with bitters.

Case of Traumatic Aphasia Successfully Treated by Trephining, and Removal of a Blood Clot from the Interior of the Cerebrum.—At a recent meeting of the Royal Academy of Medicine in Ireland (*The British Medical Journal*) Mr. C. B. Ball read notes of the following case: F. B., aged twenty-six, admitted September 1, 1887. He stated that he had been struck on the head with a penknife ten days before coming under observation. He presented himself at another hospital immediately after the accident, but his case was not considered sufficiently urgent for him to be detained as an in-patient. Since the accident he had difficulty in using the right word, as, for instance, he said he had a "man" in the side of his head when he meant "pain." He said that the difficulty of speaking and pain in his head had increased considerably during the last few days. Upon examination a small scab was found adherent to the scalp, over the squamous portion of the left temporal bone; this, when detached, showed a cicatrix apparently extending deeply through the temporal muscle, but the wound was quite healed. Classifying the symptoms presented by this patient during his stay in hospital, it was found that his motor aphasia was to the extent of being unable to name articles which were shown to him correctly, while in speaking he constantly used wrong words or parts of words. Although he was able to write his name correctly, and with rapidity, and copy writing, he was unable to write from dictation, or to write sentences which he originated himself; his attempts to do so did not show a single properly formed character. Word blindness: When given a book to read he said the words ran into one another, and then he could not make them out. Word deafness: When asked questions his answers were sometimes so irrelevant as to suggest that he had not appreciated the meaning of the query correctly; and when told to put out his tongue he opened his mouth only, but when he was set an example he at once protruded the tongue. This was frequently tried with the same result. There was no paralysis whatsoever to be detected of any of the voluntary muscles when he came under his observation; and, judging from the fact that immediately after the accident his case was not considered sufficiently grave for admission into another hospital, there could not have been at that time any overt paralysis. Five days after his admission his symptoms had so much increased that it was determined to operate. A flap was turned down, including a portion of the temporal muscle, and containing in its centre the cicatrix; this disclosed a wound of the squamous portion of the temporal bone, of a size and shape likely to be produced by a small blade of an ordinary penknife, held horizontally, with the back of the knife toward the patient's back, and the edge looking directly forward. A medium-sized trephine was now applied, and a circle cut out, containing in its centre the cut in the bone; this was attended with some difficulty, as the lower part of the circumference was exceedingly thin, while the upper portion was tolerably thick; the piece was removed without injury to the dura mater by the trephine. It was found that the knife had perforated the dura mater and brain. The wound in the dura mater was enlarged, in doing which the large posterior branch of the middle meningeal artery was divided, and gave some little difficulty to control; this vessel had very narrowly escaped injury by the penetrating knife. A sinus forceps was gently passed along the brain wound, and the blades separated, when dark-colored blood presented, which was gradually extruded by the internal brain-pressure. Some more fragments of clot were removed by the sinus forceps, and by a stream of weak perchloride of mercury solution from a syringe. A drainage-tube having been introduced, the flap was replaced and held in position by deep sutures, including the temporal muscle. On the evening of the same day the patient was much more rational, and carried on a long conversation, with very few mistakes in his selection of words. Next morning he was again more aphasic, and it was found that the drain had become blocked. Upon freeing it a considerable quantity of fluid, containing broken-down blood clot, was removed, and his power of speech improved. He made an uninterrupted recovery, and regained completely his power of writing, reading, and speaking. In this case he believed the knife penetrated the superior temporo-sphenoidal convolution, traversed the fissure of Sylvius, and probably injured Broca's convolution, and that his symptoms were due to a blood clot in the fissure of Sylvius, which was breaking down, and which was evacuated by timely surgical operation.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

THE PERCENTAGE OF INCOMPETENT GRADUATES FROM MEDICAL COLLEGES.

THE *Journal of the American Medical Association* gives an interesting summary of the work of the Medical Examining Board of Virginia, and deduces therefrom some conclusions which are worthy of wide attention.

The Examining Board in question is a body authorized by law to license practitioners of medicine after they have passed a satisfactory examination. The Board does exactly what it has been the effort of the medical profession of this State to do—an effort which has been defeated by the selfish policy of the medical colleges.

Since the organization of this Board, January, 1888, there have been 223 applicants in all, 49 being rejected—21.97 per cent. Of the applicants 212 were graduates; 45 were rejected—21.69 per cent. There were 11 non-graduate applicants, 4 of whom were rejected—36.36 per cent.—and 2 had not completed their examinations at the time of the report. In a table are given the names of 27 colleges from which applicants have come before the Board; excluding the University of Heidelberg, we have 26 American colleges; 13 of these sent 51 applicants, all of whom passed; 13 others sent 156 applicants, with an average of 34.73 per cent. of each rejected—more than one-third.

Our contemporary adds: "Counting first and second applicants, we see that 228 graduates were examined, and 54 failed—23.68 per cent. From 1877 to 1887 inclusive, there were 36,097 graduates from medical colleges of the United States. They held documents that are considered as entitling to practise in the majority of our States and Territories. But according to the above figures, if these 36,097 had gone before an efficient examining board, 8,300 *would have been rejected!*"

If we may judge by the work of the Virginia Board, then nearly one-fourth of the graduates of our American Medical Colleges cannot pass a reasonable examination by an unprejudiced Board, and are not fit, so far as examination-tests show, to practise medicine.

This is an unpleasant showing, and one which speaks severely against the carefulness and conscientiousness of our medical institutions for teaching.

It may be said that the best material does not go before this Virginia Board, and that if it were to examine all the graduates of each college, the percentage would be lower. Such an objection is justifiable so far as it goes, but the fact remains that one-fifth of the medical graduates who go to Virginia to practise are found incompetent.

It is well known that an effort has been made by the Faculty and Students of the Medical College of Virginia to change the law so as to exempt Virginia graduates from its provisions. This is a confession of weakness unworthy, as it seems to us, of the colleges of that State. If the local institutions cannot educate students sufficiently to pass the Board examinations they had better go out of the business. As a matter of fact their record is a good one, and does not call for the effort they are making to weaken the force of a good law.

If the Virginia Board continues its work as faithfully as in the past, it will do an immense service to medical education, not so much through its careful examinations and purgation of the plethoric mass of annual graduates as by the example of a successful application of the principle that the licensing power should be taken from the colleges and placed in the hands of an independent board.

THE YELLOW FEVER MICROBE.

IT is well known that Dr. Domingos Freire, of Rio Janeiro, has for several years contended that he has discovered the microbe of yellow fever, cultivated and attenuated it, and used it in making protective inoculations. It is also part of history that M. Paul Gibier was sent from Paris to examine into these alleged discoveries, and that Dr. Sternberg was sent by the United States Government for the same purpose. Both gentlemen reported that Freire's discoveries amounted to nothing, that his methods were faulty, his observations inaccurate.

Dr. Domingos Freire has recently made a reply to his critics, an abstract of which we find in the *Medical Times*.

Dr. Sternberg is dismissed in a foot-note, in which Dr. Freire says that the American sojourned but a short time in Brazil, at a time when there was no epidemic; he examined but one sporadic case, and made no autopsy; in fact, he had not the materials with which to form an opinion of even mediocre value. Dr. Sternberg, he adds, supplies the lack of arguments by distorting the facts, and inventing imaginary calculations and coarse sophisms, in order to uphold his preconceived idea that this vaccination against yellow fever is chimerical.

This is a somewhat severe indictment of a $10,000 commissioner, and it is certainly quite out of accord with Dr. Sternberg's known character and previous work. We can say personally that we have not observed any coarse sophisms in the doctor's works.

But it is to M. Gibier that Dr. Freire devotes most of his attention. That gentleman, though repudiating Freire's discovery, announced that he had himself found a microbe which might be the germ of yellow fever. He says, "I have isolated, from the black contents of the intestine, by a particular process, a micro-organism whose culture let fall in less than twenty-four hours a deposit of thick, black flakes and powder. The sides of the culture-tubes are blackened by the secretions of the microbes. I have inoculated with a drop of this culture the intestines of guinea-pigs, which die in twelve to sixteen hours, with the intestine extremely congested, and containing a blackish and sanguinolent matter." All these results Freire claims to have obtained already. On page 203 of his book entitled, "Doctrine microbienne de la fièvre jaune et ses inoculations préventives," published in 1884, he says: "A large number of cultures have presented a black deposit, which we have shown to our students and to Brazilian and foreign physicians. When Professor Rebourgeon, in the laboratory of the faculty, repeated our experiments and researches, he had occasion to verify for himself the truth of this fact, curious and full of interest for the pathogeny of yellow fever."

This paragraph shows, perhaps, that Freire had isolated the same microbe, but not that he really appreciated its life history.

He claims, however, that in addition, Finlay at Havana, and Matienzo at Vera Cruz, independently found and cultivated the same microbe.

Dr. Freire's pamphlet is an interesting one, and it will, no doubt, elicit interesting discussions.

HOMICIDAL PARANOIA AND THE WHITECHAPEL MURDERER.

For some weeks past a certain district in London has been the seat of a series of frightful murders. The victims have always been women, and these were prostitutes of the lowest class. The crimes have been committed at the dead of night, and always in nearly the same fashion, the neck being cut, and then the victim disembowelled, and in some cases the uterus taken out. Six murders have so far occurred, and the author of the crimes has not yet been discovered.

Beyond all question the work is that of a lunatic. Such forms of insanity are rare, but not unknown. The subjects are cases of monomania of a primary or degenerative character. The general term paranoia includes the type, but those murderers are paranoiacs who are affected with morbid and bestial propensities of the lowest and most revolting nature. The insane murderers who do the kind of work that has been accomplished at Whitechapel are of the same class as those who have sexual aberrations or cannibalistic and necrophilic propensities. Indeed the Whitechapel murderer seems to show a form of necrophilis—a name given to the propensity to violate dead bodies, and sometimes associated with the propensity to murder.

Some five years ago our readers may remember that a long series of murders was committed in Westphalia by a lunatic. In all cases the victims were young girls, who were violated and then killed in the most horrible and revolting manner.

Homicidal mania is a very common symptom and occurs in many forms of insanity. It is sometimes the result of a delusion, but more often springs from an overwhelming impulse or an imperative feeling passing suddenly beyond control. Homicidal maniacs of these types kill without premeditation, or at least without any careful planning to escape punishment. Their crimes are single.

With the homicidal paranoiac it is different. Murder causes in him a distinct delight. The sight of his slaughtered victim is a source of exquisite material enjoyment. He has no delusions, he has simply a horribly brutal appetite to gratify and no moral feeling to interfere with its indulgences. He understands the nature of a crime intellectually and appreciates its legal consequences. Hence he develops sometimes an extraordinary cunning in evading the just consequences of his acts.

The problem of what to do with these monsters is generally settled practically by the intense horror and anger excited by their deeds. Though lunatics, they are hung, either by lynch law or through the agency of the proper courts. Perhaps it would be more just and humane not to kill such congenital criminals. The problem is a difficult one, and involves the purely social question: What method in the end is for the best interests of society, to kill or to imprison for life? As society develops humaner instincts and broader views of the nature of crime, and of the crookedness born into certain persons' minds, no doubt imprisonment will be the fate of most of the unfortunate moral monsters whose crimes shock and infuriate us. At present, however, the Whitechapel murderer, if found, will, we fancy, find but little mercy in the civilized city of London.

THE CLASSIFICATION AND CAUSES OF IDIOCY.

A great deal more attention has been paid to the subject of insanity, its cause, prevention, and increase, than to that of idiocy. Yet there are in this country nearly as many idiots as insane, and the rate of their increase has been nearly as rapid. The following figures show this. Total number of idiots in the United States: 1850, 15,787; 1860, 18,930; 1870, 24,527; 1880, 76,895.

The number of idiots, as given by the census, at one time equalled that of the insane. The latter class, however, is now slightly in excess, owing to the excess of adults in our population. But the existence of one idiot (scientifically so classed) to every six hundred and fifty-two persons of developed mind, should awaken a somewhat larger interest in these unfortunates than has heretofore been the case.

There are, according to Dr. Down, three forms of idiocy: The congenital, the accidental, and the developmental.

The congenital form includes those cases in which the defect in the brain is the result of progressive family deterioration; hereditary taint increased by intermarriage until the climax is reached. The health of the mother is an important factor in causing these types. Violent emotions, chorea, epilepsy, and eclampsia may be of the gravest import to the offspring. Periods of political excitement, wars, etc., all increase the roll of feeble-minded children, and the effect in certain instances has been demonstrated with almost mathematical accuracy. Severe emotional disturbance even in the father may lead to a similar result, but apparently with less certainty. Alcoholism, as might have been expected, is responsible for a very tangible share of mental and physical degeneracy, and in Norway, after the removal of the spirit duty, insanity increased fifty per cent., and congenital idiocy one hundred and fifty per cent. Syphilis is not, it appears, an important factor, but phthisis is said to exercise a very marked influence, existing as it did in twenty-five per cent. of the fathers and twenty per cent. of the mothers.

We must remember, however, the very great frequency of phthisis in all classes.

Quoting from an analysis of Dr. Down's lectures in the *Medical Press*, we find that the influence of trades and professions is possessed of especial interest. Out of four hundred cases with fair social antecedents, the lecturer found that seventy-five per cent. were the children of merchants, county gentlemen, officers in the army and navy, and members of the titled aristocracy; no less than twenty-five per cent. were the children of members of one or other of the three learned professions. It is comforting to know that while three per cent. were the offspring of lawyers, and four per cent. of members of the medical profession, no less than eighteen per cent. were the children of members of the clerical profession. On the other hand, the legal profession gives birth to eleven per cent. of the present men of eminence, the medical to nine per cent., and the clergy to only four per cent.

With regard to accidental idiocy, Dr. Down is known to place much stress upon accidents at the time of labor. He says that, while instrumental interference *might* have caused about nine per cent. of the cases, in more than twenty per cent. there was a history of suspended animation or a hitch of some kind at birth. Prolonged labor and consequent pressure, is a much more potent factor than mechanical injury from the use of instruments. Sunstroke, the administration of opium, and sexual excitement wilfully induced by nurses to keep their charges quiet, are all responsible for a part of the number, but meningitis and encephalitis doubtless lead to a large proportion of the cases.

Cerebral hemorrhages are also elements of some frequency in causing feeble-mindedness.

Of the developmental variety, or those whose intellectual development is arrested during dentition or at puberty, Dr. Down says: These are the cases which break down by over-excitement in babyhood and by "over-pressure"—that is, pressure too great for them with inherent want of stamina at second dentition and puberty. Such cases are the more important, seeing that with due care they may in many cases avoid the breakers on which their intelligence would founder.

THE FIELD OF THE GENERAL PRACTITIONER.

A GREAT hue and cry has been raised by our English exchanges over the attempt to publish a "Dictionary of Specialists." We take it that the dictionary will be little more than a medical register of the different specialists, giving the qualifications of each. Such a publication irresponsibly issued would no doubt be open to great abuses, and we do not venture to argue against the storm of aggrievement and invective roused by the proposed publication. There is always something a trifle amusing, however, in the ponderous way with which our English brethren receive a shock to their sense of the conventional, even if, as in this case, there is good cause for its being disturbed. One would think just now that the foundations of British Medicine and Morals were being sapped through the calculated malice of an amateur lexicographer.

The evils and abuses of specialism which are again being heralded by our esteemed contemporaries are patent to everyone, and they have been often enough discussed in these columns. Sometimes, however, it seems as though needless attempts were being made to frighten the general practitioner into an idea that the time is coming when all medicine will be specialized and the family doctor be left without a field for his work.

Such a state of things is impossible, as will be seen by a little reflection.

If one looks over the lists of causes of death he will see that the infectious fevers produce one-fourth of all the mortality, each death representing five to ten cases of sickness; he will find that phthisis and bronchitis produce nearly one-fifth, pneumonia a twelfth, Bright's disease a fifteenth, of the annual deaths. One-third of this mortality also occurs among children under five years of age, too young to be very much specialized, while about one-twenty-fifth of cases of severe sickness are obstetrical. Practically, all acute illness, all obstetrics, pædiatrics, and a large proportion of accidents, injuries, and minor chronic ailments must remain under the domain of the general practitioner.

There is certainly field enough for him.

The worst evils of specialism now are those resulting from the fact that too many are rushing to these narrower channels, forgetting that the field is small and must remain so.

THE ALKALINE TREATMENT OF YELLOW FEVER.

IT is a fact true of yellow fever, as well as of all self-created fevers, that treatment must be individualized, and must be more or less symptomatic. Any attack of yellow fever cannot be regulated by any measure at present known. Experienced physicians will feel some doubt of the value of any routine line of treatment, no matter how well supported by theory and statistics. Dr. George M. Sternberg, however, has ventured to propose a special treatment for yellow fever based on certain pathological and physiological considerations (*Therapeutic Gazette*).

It is well known, he says, that in yellow fever the urine and the vomited matters are highly acid. The intestinal contents, also, have usually a more or less decided acid reaction. A microbe, therefore, capable of multiplying in the stomach and intestine in this disease must be able to grow in an acid medium. But aside from this theoretical reason for prescribing alkalies, the highly acid condition of the secretions furnishes an indication for such a treatment, and Dr. Sternberg therefore proposes the following formula:

℞. Sodii bicarb.	10 grms. (gr. 150).
Hydrarg. chlorid. corrosiv.	2 ctgm. (gr. $\frac{3}{10}$).
Aquæ puræ.	1 litre (1 quart).

M. Sig.—Fifty grammes (about oz. $1\frac{3}{4}$) every hour; to be given ice cold.

The house-physician at the Garcini Hospital has sent a record of twelve cases treated by the alkaline and bichloride method, and it appears that all of them recovered. While these twelve cases were being treated, and a little before, eight cases were treated in the same institution by other methods, and five of the eight died.

It is admitted that the bichloride in safe doses does very little toward intestinal antisepsis, and the formula above given is not a rational one, so far as intestinal disinfection is concerned. But the results, so far as reported, are creditable to the alkaline method.

News of the Week.

Professor Charcot's Fee for treating the Emperor of Brazil was $8,000.

Railway Surgery.—We have a unique specialty among medical journals in the *Journal of the National Association of Railway Surgeons*, devoted to the interests of railway surgery.

Yellow Fever in the Year 1887 was present in Mexico, Brazil, Central America, Cuba, Jamaica, and at Tampa and Key West, Florida, but chiefly at Guayaquil, Havana, Key West, and Santiago de Cuba. The total number of deaths during the year was 1,270. Of these 147 occurred in Florida. The loss of life from yellow fever in Florida, during the recent epidemic, has not been quite double the loss of the year before.

The Yellow Fever Epidemic at Jacksonville is on the decline. Up to October 4th there have been 2,896 cases and 270 deaths.

Dr. Abner O. Kellogg, for many years first assistant physician at the Hudson River State Hospital, Poughkeepsie, died at Kentland, Ind., on September 21st, from paralysis. He was born in Madison County, N. Y., about seventy years ago. Dr. Kellogg was in general practice till 1861, when he was appointed first assistant at the Utica Insane Asylum. He was appointed at Poughkeepsie in 1870.

Mesmerism and the "North American Review."—An excellent example of the pernicious activity of bumptious ignorance is shown in a recent article in the *North American Review* on mesmerism. The contributors to this journal are supposed to write with some authority, but the author of the article in question seems quite unacquainted with the recent work and conclusions of scientific men. Nor does he seem to be aware of the harm which articles upon this subject, written without caution, may produce. Any work which would encourage experiments in parlor hypnotism deserves to be severely condemned.

Weighing Thoughts.—A correspondent of the *American Practitioner* writes from London that Professor Mosso has been studying the variations of the circulation in the hand and head by means of the plethysmograph. His observation of the changes in the amount of blood in the hand during various kinds of mental activity are old and of no especial significance. In addition, however, he now has a balance on which the horizontal human body may be poised. With this he has found that one's thoughts may be literally weighed, and that even dreams or the effect of a slight sound during slumber turns the blood sufficiently to sink the balance of the head. The changing pulse even told him when a professional friend was reading Italian, and when Greek, the greater effort from the latter duly affecting the blood-flow. The practice of weighing one's words has been advised since antiquity; that of weighing the thoughts is perhaps fully as important. It would be a great help to editors and presidents of medical societies if an article sent in could be indorsed: "Weight of thoughts embodied, 1 gramme and 20 milligrammes." A minimum weight-limit might be established for original articles. A great future lies before Professor [Mosso's plethysmographic horizontal balance.

A New Hospital.—The papers announce with much flourish the completion of a new homœopathic hospital at Detroit, Mich., at a cost of $100,000. The sum mentioned does not go far in hospital building and maintenance. It is unfortunate, however, that even such an amount should be wasted in giving support to a dogma already practically extinct in intelligent communities.

The New York State Medical Association holds its fifth annual meeting at the Hotel Brunswick, in this city, October 9th and 10th.

Medical Colleges and the License to Practise.—Dr. William Osler, of Philadelphia, sends to the *Journal of the American Medical Association* some forcible remarks regarding the subject of separating the licensing and the teaching powers. "It is not a function of the university to grant the license to practise. That the M.D. degree carries this privilege is a modern usurpation, which does not extend to degrees in other faculties. It is a function of the State, to be exercised either directly, as is done in Germany, or indirectly, by the profession organizing and appointing suitable examiners. The struggle is between the colleges and the profession, and I would refer anyone who may feel doubtful as to the issue of the fight to an address which I delivered in 1885, when President of the Canada Medical Association (*Med. News*, 1885, ii.), in which I sketched the organization of the profession in the Provinces of Ontario and Quebec, which led, in the former Province, to the complete subjugation of the schools. You may be surprised, sir, at these sentiments from a dyed-in-the-wool school-man, but I feel convinced that the future of medical education in this country lies largely in the establishment of State Boards, such as exist in Virginia and North Carolina, which shall (1) control the entrance examination, (2) regulate the curriculum, and (3) grant the license to practise."

In Honor of Esmarch.—The last meeting of the Medico-chirurgical Society, held October 1, 1888, was unusually well attended, in honor of Professor von Esmarch, who had received and accepted an invitation to address the Society. After the close of official business, supper was served and impromptu toasts were proposed and responded to. Among those who made remarks may be mentioned Dr. L. Weber, the President of the Society, who toasted the honored guest of the evening. Professor von Esmarch. The latter briefly expressed his thanks and appreciation of the honor conferred upon him by the Society's invitation. Drs. Sayre, Detmold, Heitzman, and Jacobi also spoke. Dr. Lange read a number of poems specially composed for the occasion, and humorously eulogistic of Esmarch.

The Specific Bacillus of Syphilis.—Julian Markuse, in the *Vierteljahresschrift für Dermatologie,* gives the results of his studies of the secretions in one hundred and sixty-one cases. He examined especially the Lustgarten syphilis bacilli and the smegma bacilli. Although these are apparently identical by ordinary methods of research, Markuse found what he considers a differential stain. He thinks, therefore, that these two bacilli are distinct.

THE CHINESE PHYSICIANS are the homœopaths of the East. The *Sei-I-Kwai Medical Journal* states that in Japan it is still thought by some Japanese, especially old men and women, that children should be treated by Chinese physicians, because their treatment is generally mild.

UNTIMELY.—A contributor to the September issue of the *Therapeutic Gazette* advocates Florida (*quoad* Orlando) as a health-resort.

FREE WHISKEY AND THE INCREASE OF IDIOCY AND INSANITY.—In Norway, after the removal of the tax on whiskey, insanity increased fifty per cent. and idiocy one hundred and fifty per cent.

THE PANCREAS can be entirely removed from dogs without loss of life or especial disturbance of functions, according to Dr. G. Martinotti. Signs of increased work thrown on the intestinal glands are found.

THE ABUSE OF LOCAL TREATMENT OF THE UPPER AIR-PASSAGES.—Two articles, touching upon the subject of the excessive operative zeal of rhinologists, have recently appeared in the *British Medical Journal*. Dr. F. de Havilland Hill says: "It appears to me that a good deal of unnecessary tinkering with Nature's handiwork is done to the septum. Some surgeons seem to think that unless the septum be perfectly straight, measures ought to be taken to rectify its faulty position. When one reads that in the space of two years one specialist has operated on one hundred and sixty-six patients for deformities of the nasal septum, in private practice alone, I think you will agree with me that in all probability his zeal for the rectangular was greater than his judgment. This is on a par with what took place when attention first became directed to displacements of the uterus—every trifling departure from the normal position was thought to require a special pessary, and to be the cause of innumerable ills; now, however, common-sense is reasserting itself, and it is allowed that the uterus need not be in exactly the same position in all women." Doubtless there has been a somewhat excessive amount of operating on the nose. Fortunately, however, even where the operations fail, very little, if any, harm can be done.

IRISH POLITICS AND THE MEDICAL PROFESSION.—*The Lancet* states that in some parts of Ireland the political agitation, and the doctrines underlying it, are having a very injurious effect on medical practice. People are apt to think that they should receive medical relief as a State right. This has long been provided for in the dispensary system of Ireland as regards the people that, by any pretence, can be regarded as poor. But it is now complained that people who heretofore have had a feeling of pride and independence, and who would go to the medical man of a district as private patients and gratefully compensate him for his services, now apply for the "red ticket" and accept gratuitous medical attendance. The Irish have long been the main-stay of free dispensaries in this city. Other nations, notably the Germans and Italians, are now pressing them hard.

PASTEUR'S INOCULATIONS FOR RABIES have not been very fortunate of late. Since June seven persons who had been bitten by rabid animals (in most cases cats) and subsequently inoculated have died.

MEDICAL CONGRESSES IN ITALY.—There is a perfect epidemic of medical congresses in Italy at present. Gynecologists, ophthalmologists, hygienists, hydrologists, have met and listened to each other's eloquence, and exchanged compliments, and recounted their triumphs to their admiring friends. The great Medical Congress which is to be held at Rome in October will be the first of its kind; and Dr. E. Maragliano and his lieutenants are sparing no pains to make it a success. About the same time another hygienic congress will meet at Bologna.—*British Medical Journal.*

EVERYONE WILL SYMPATHIZE with the extraordinary and unjust suit which has been brought against Dr. Samuel C. Vander Poel, of this city, recently. Some weeks ago, the accounts state that Dr. Vander Poel diagnosticated the illness of a little daughter of Charles Dawson, of Syracuse, N. Y., who was spending some time with his family at the Larkins House, Watch Hill, L. I., as scarlet fever. Mr. Larkins, the proprietor, relying on the diagnosis of another physician, denied that the child was suffering from the disease, and the Dawson family remained at the hotel. The other guests, hearing of Dr. Vander Poel's diagnosis, left the place. Mr. Larkins immediately brought suit in Rhode Island against Dr. Vander Poel for twelve thousand dollars damages. Dr. Vander Poel says that his diagnosis was correct and that he has been sustained by the Board of Health of Westerly, R. I., and some prominent physicians. We understand that Dr. Vander Poel intends fighting the suit.

THE POISON IN THE CIGARETTE.—Dr. William L. Dudley, as the result of some carefully conducted experiments upon the combustion of cigarettes (*Medical News*), concludes: 1. That carbonic oxide is the most poisonous constitutent of tobacco smoke. 2. That more injury results from cigarette than cigar or pipe-smoking, because, as a rule, the smoke of the former is inhaled. 3. That cigarette smoking without inhaling is no more injurious than pipe or cigar-smoking. 4. That the smoke of a cigar or pipe, if inhaled, is as injurious as cigarette smoke inhaled. 5. That the smoke from a Turkish pipe, if inhaled, is as injurious as that of a cigarette inhaled.

THE "OMAHA CLINIC" is the title of a new monthly journal edited by Dr. J. C. Denise. Nebraska now has two medical colleges and one medical journal. The journal is a good one.

A CODE OF ETHICS FOR DENTISTS.—At a recent meeting of the British Dental Association, Dr. Flack read a paper on "Dental Ethics" in which he advocated the establishment of a code of ethics. Whether this is to be a new code or an old code appears to be a matter for furture deliberation.

PHEBO-SCLEROSIS is a systemic condition analagous to arterio-sclerosis. It has recently been studied by Dr. Sack, of Dorpat, who finds it much more frequently present than has been supposed. It stands in close relation, etiologically, to arterial sclerosis.

HEADACHE AND SALT.—Dr. Rabow has found that an attack of migraine may often be averted by a teaspoonful of table salt taken upon the first appearance of the premonitory symptoms.

Society Reports.

SEVENTH INTERNATIONAL CONGRESS OF OPHTHALMOLOGY.

Held in Heidelberg, August 8, 9, 10, *and* 11, 1888.

PROFESSOR DONDERS, OF UTRECHT, PRESIDENT.

(Special Report for THE MEDICAL RECORD.)

WEDNESDAY, AUGUST 8TH—FIRST DAY.

AT the opening session PROFESSOR DONDERS delivered the

PRESIDENT'S ADDRESS

in both German and French, each sentence being read first in one language and then in the other. He recalled the advances made in ophthalmology in recent years, mentioning particularly the labors of Graefe and Helmholtz.

DR. JAVAL, of Paris, presented a communication on

OPHTHALMOMETRY,

and showed a modification which he had made in the ophthalmometer of Helmholtz, with the object of making it of greater practical utility. In his instrument one of the glass plates was fixed, and the rod with three mirrors was replaced by a gas-pipe with three holes giving three flames. The drum registering the movements of the plate had been enlarged, and it was possible to read directly in dioptrics the value corresponding to the displacement of the plate. The final modification had been the substitution of the glass plates by a birefracting crystal, which gave a more distinct image.

DR. DUFOUR asked what were the relations between corneal astigmatism and total astigmatism of the eye, and also whether the curvature of the cornea varied with the blood-pressure and with the heart's action.

DR. JAVAL replied that he had noticed a rhythmical modification of the corneal curvature synchronous with the radial pulse. As to

THE RELATION BETWEEN CORNEAL AND TOTAL ASTIGMATISM,

the first most commonly represents the second. There are, however, two exceptions: 1. In irregular corneal astigmatism there exists also irregular crystalline astigmatism. In this case the crystalline has undergone a slight rotation around its vertical axis. 2. In young persons corneal astigmatism is wholly or in part masked by an astigmatic contraction of the crystalline. The total astigmatism is then much less than that of the cornea, but it becomes equal to it after the thorough use of atropine. Accommodation in astigmatics takes place in two stages: there is first a slight effort of accommodation, and then rotation of the crystalline around an axis situated in the frontal plane, in order to correct the corneal astigmatism.

DR. GRAEFE, of Halle, read a paper on the

ACTION OF THE INTERNAL RECTUS MUSCLE

in associated lateral movements and in accommodative movements of convergence. He thought there was a distinct nervous centre for the production of each of the two sorts of movement executed by the internal rectus muscle, viz.: convergent or accommodative, and associated lateral movements. This belief is strengthened, he said, by clinical facts, since it is not uncommon to see one set of these movements abolished while the other remains unaffected.

DR. LANDOLT supported the reader of the paper in this view, and said that he had formerly reported cases of tabes in which there was abolition of convergence, with normal associated lateral movements.

DR. SAMELSOHN, of Cologne, referred to a case of congenital strabismus of the left eye, which he had seen, in which the associated movements to the left were normal, but those to the right were abolished. Convergence was possible, and so were the movements to the right of each eye separately. There was no diplopia.

DR. LANDOLT then read a paper on

NON-PARALYTIC STRABISMUS.

The absence of binocular vision and of accommodation predisposes to this affection. Among the exciting causes are the relation that exists between convergence and accommodation, the want of harmony between the retina and the motor system of the eye, abnormally wide separation or deformity of the orbits, and faulty insertion or defects in length or strength of the motor muscles. On the boundary line between this form of strabismus and the paralytic variety is that accompanying neurasthenia, hysteria, locomotor ataxia, and other affections of the nervous system. Recent cases may often be relieved by the stereoscopic exercises of Javal. In convergent accommodative strabismus, rest to the eyes, mydriatics, and convex glasses are especially indicated. Tenotomy is to be practised only when the antagonistic muscles are strong, and care must be taken lest exophthalmus result; the author preferred advancement of the tendon. In divergent strabismus mild measures are less efficacious, and it is necessary to resort earlier to operation. Tenotomy is indicated only in moderate degrees of strabismus, when the muscles are normal, and advancement of the internal recti is to be recommended when the muscles are weak. Vertical strabismus often accompanies marked degrees of lateral deviation, and disappears when they are cured; or, on the other hand, it may be caused by too active treatment of the latter.

DR. SCHWEIGGER said that binocular vision was sometimes present in the cross-eyed, as could be demonstrated by forcing the eye into its natural position under the influence of cocaine.

DR. JAVAL said that simultaneous vision might exist in both eyes in cases of strabismus, but this was very different from binocular stereoscopic vision.

DR. KNAPP favored muscular advancement, which left the eye with greater motility and did not expose to the danger of post-operative exophthalmus. Care must be taken, however, to carry the sutures in the episcleral tissue to the edge of the vertical diameter of the cornea. If there is found to be over-correction, one of the sutures can be removed early on the second or third day.

DR. SCHWEIGGER said that over-correction was not to be feared, as there was a natural tendency to return to the normal position in the course of time.

DR. DE WECKER said that he did not practise muscular advancement any more, but in certain cases he resected a portion of the muscle.

DR. REYMOND, of Turin, then read a paper on

THE ETIOLOGY OF STRABISMUS,

referring particularly to the influence of the relative amplitude of accommodation, and of convergence in the production of this condition.

DR. STILLING, of Strasburg, followed with a communication on

THE RELATION OF REFRACTION TO CRANIAL CONFORMATION.

The elongation of the eyeball, producing myopia, is caused by the pressure of the muscles, especially of the superior oblique. When the orbital vault is low this pressure is greatest. The author has found, from a long series of observations, that the orbital vault is low in myopes and high in hypermetropes. The former have a wide face and square head; the latter an elongated and narrow face.

DR. SCHMIDT-RIMPLER said that the development of the orbit might be secondary to that of the eye. The results of many examinations of the eyes of students in Marburg were not in support of this theory.

DR. WEISS had made measurements of the orbit on the living and the dead, and had often found these confirmatory of the author's views. But in anisometropes there is usually no difference between the two orbits.

THURSDAY, AUGUST 9TH—SECOND DAY.

DR. GAYET, of Lyons, read a paper on

THE TREATMENT OF CATARACT.

He began with the assertion that cataract could be cured only by operation, and that it was useless, therefore, to waste time with medical measures. There are three forms of operation of use in the cure of cataract, viz.: 1. Discission; this is suitable for soft cataracts, and its field of usefulness is growing more limited as the method by extraction is becoming perfected. 2. Displacement, or reclination, which is almost never indicated. 3. Extraction, which is the most generally useful method, and to which all others must in time yield. In the present state of science the extraction must be made without the capsule, but attempts at removal of the lens with its capsule are scientific, since this is an ideal after which we have a right to strive. Extraction necessitates opening the cornea in the region corresponding to the anterior chamber. The exact location of the wound cannot be settled by any fixed rules, for all positions have their advantages and their disadvantages. The opening should be large, better too large than too small. Iridectomy, as a rule, is not necessary. The discission of the capsule should be made at the same time as the opening of the cornea, and with the knife. The expulsion of the crystalline is effected by the combined pressure of the fixation forceps and of the curette. In clearing the pupil of fragments no instrument should be used, a stream of water directed on to the wound and eddying around in the anterior chamber, alternating with massage, suffices to remove all débris and render the pupil clear. All these manœuvres are rendered easy of performance by the use of cocaine, and certain in their results by antisepsis. The only accident that is to be feared is the entanglement of the iris. This may be caused by spasm, by reflex glaucomatous tension, or by the swelling of the fragments remaining. The first cause is to be avoided by the exercise of the most scrupulous care, and the third by observing the precaution to remove as completely as possible all debris. It is impossible always to foresee and prevent the operation of the second cause. Opacity of the capsule that remains is a frequent complication, and one that is to be dreaded, for secondary operations are uncertain and dangerous.

DR. SCHWEIGGER, of Berlin, read a paper on

THE HISTORY OF CATARACT OPERATIONS.

He said it was impossible to compare justly the methods of Daviel and of Graefe, since the employment of cocaine and antiseptic measures had, of late years, profoundly modified the results of all operative procedures. He reported 168 cases, occurring in his own practice, of extraction without iridectomy, but with cocaine and antisepsis, all of which were successful. He thought that iridectomy was dangerous to vision.

DR. DE WECKER always used eserine, which prevented glaucomatous complications, but advised against the use of atropine, which might cause increased intra-ocular tension.

MR. CRITCHETT, of London, recalled the results obtained by his father in the employment of these two methods, viz. : with and without iridectomy. He believed that the latter was the more sure.

DR. GALEZOWSKI, of Paris, advised, in order to avoid hernia of the iris in Daviel's operation, puncture and counter-puncture in the sclerotic, and then closure of the eye, which should be left undisturbed for six days.

DR. KNAPP, of New York, favored the operation for cataract without iridectomy. He compared the eye to a steam-boat, and iridectomy to the safety-valve which should be called upon to act but very rarely.

MR. JESSOP, of London, presented a communication on

THE PHYSIOLOGICAL ACTION OF THE INTRA-OCULAR MUSCLES.

Like the muscles of the intestines, and of the blood-vessels, these also have two sets of nerves with opposing functions. The short ciliary nerves excite contraction of the iris and myosis, the long ciliary nerves dilatation of the pupil and mydriasis.

DR. COCCIUS, of Leipzig, read a paper on

THE RÔLE OF THE TENSOR MUSCLE OF THE CHOROID.

During accommodation, the posterior surface of the crystalline lens vibrates more or less rapidly, these movements being especially pronounced when there is liquefaction of the vitreous. The vitreous body feels first the influence of the tensor muscle of the choroid, and it thus compresses the crystalline, inducing in it a change of form.

DR. DE WECKER then presented a communication on the

TREATMENT OF PERSISTENT LACHRYMATION,

by means of removal of the palpebral lachrymal gland, which he believed to be the one that secreted the tears excited by emotional causes. He had performed the operation twenty-five times, and in all had succeeded in causing a complete cessation of lachrymation, while the lubrication of the conjunctiva was still perfectly performed.

DR. GRUENING, of New York, said that profuse lachrymation was often due, directly or reflexly, to affections of the nose, and the cure of these not infrequently sufficed to correct the hypersecretion of tears without the necessity of resorting to extirpation of the palpebral gland.

DR. EVERSBUCH, of Erlangen, in cases of inveterate lachrymation, removed the orbital gland through a cutaneous incision in the fronto-palpebral fold. In order to prevent subsequent ptosis, he united the orbicular muscle to the frontal periosteum by sutures. He suggested that the operation proposed by the last speaker might expose to the danger of xerosis of the cornea.

DR. COHN, of Breslau, showed some

PHOTOGRAPHS OF THE FUNDUS OCULI

obtained by means of a flash light. He said that it was very difficult to obtain good photographs of the fundus.

DR. HOWE, of Buffalo, thought that the difficulties of photographing the fundus were not invincible, and he exhibited some views which he had taken a year ago.

DR. KNAPP said that some quite good reproductions of photographs of the fundus had been published in the *Archives of Ophthalmology*. Instantaneous photography was no new thing in America.

DR. CRAINICEAU, of Bucharest, read a paper on

THE ETIOLOGY OF MYOPIA,

in which he reported the results of examinations made by him of the eyes of school-children in Bucharest and Buda-Pesth, showing that myopia increases in frequency and amount from the lower to the higher grades in the schools. He advocated the adoption of a uniform system of examination.

DR. DÜRR, of Hanover, reported five cases of

MEGALOPHTHALMIA,

in which he had found that the superior oblique muscles presented a greater obliquity than normal, and where the muscle passed around the globe there was a well-marked groove on the surface of the sclera. The result of this was compression, more or less marked, of the vasa vorticosa.

Friday, August 10th—Third Day.

Dr. Priestly Smith, of Birmingham, read a paper on

GLAUCOMA.

Glaucoma is the pathological increase of intra-ocular tension with its consequences. The increased tension is the main element of the affection, and a glaucoma without augmented intra-ocular pressure is merely a glaucoma which happens to be seen during a remission of this tension. The causes of this increased intra-articular pressure are to be found in: 1, The state of the secreting organs; 2, the condition of the emunctories; and 3, the humors of the eye. The vitreous and aqueous humors are secreted by the ciliary portion of the uveal tract. The aqueous escapes through the angle of the anterior chamber—the "angle of infiltration;" the vitreous escapes through the pupil, but very slowly as compared with the aqueous humor. The tension remaining the same, it is obvious that a serous fluid will escape much less easily from the anterior chamber than a physiological saline solution. Now the principal elements in the increase of intra-ocular tension are: 1, Hypersecretion for the ciliary processes; 2, obstruction in the angle of infiltration; and 3, serosity of the humors. The first is occasionally the exciting cause of an exacerbation, but the glaucomatous process cannot be attributed to a continual hypersecretion. Obstruction at the angle of infiltration is present in most cases of glaucoma, yet it exists in some cases in which this condition is not found. Serosity of the humors is present in several forms of glaucoma, and is the chief element in its production when the affection is secondary to serous iritis and to keratitis complicating iritis. When the cause is evident the affection is called secondary glaucoma, but when the cause is not discoverable it is called primary glaucoma. Leaving out of consideration the cases of serosity of the aqueous humor, it has been shown that in all forms of secondary glaucoma the iris is pushed forward. In acute primary glaucoma the base of the iris is pushed forward by the swollen ciliary processes, and in many cases these latter are pushed out by the crystalline and the zonula of Zinn. The chief predisposing cause of glaucoma is a narrowed circumlenticular space, and the predisposition to the affection consequently increases with age, since the crystalline enlarges with advancing years. Smallness of the cornea seems likewise to predispose to primary glaucoma. Measurements made with a keratometer on the eyes of two hundred and twenty-seven individuals showed an average diameter of 11.52 mm. In fifty-two persons suffering from primary glaucoma the average diameter was 11.02 mm. Senile changes in the vitreous, offering an obstacle to filtration toward the anterior chamber, should perhaps be reckoned among the predisposing causes, and perhaps also, though in less degree, rigidity of the sclerotic and senile degeneration of the vessels. The exciting causes are all those influences which produce congestion. The steady progress of glaucoma is due to the fact that compression of the veins of the choroid gives rise to congestion of the ciliary processes and compression of the angle of infiltration.

Dr. Snellen, of Utrecht, followed with a paper on

THE TREATMENT OF GLAUCOMA.

In posterior glaucoma (when there is diminution of the anterior chamber), myotics are useful, but in anterior glaucoma (enlarged anterior chamber) they are injurious. The opposite is true of mydriatics. Sclerotomy is indicated in all cases of increased intra-ocular tension; it gives exit to the serous humor, frees the periphery of the iris, and re-establishes the disturbed circulation. The section from without inward with the lance-knife is preferable to section in the opposite direction with the cataract knife, since there is thus less danger of prolapse of the iris. The myotics are indispensable in sclerotomy, since they favor the escape of the serous humor, cause contraction of the uveal tract, and dilate both the canal of Fontana and the sub-choroidean space. Excision of a segment of the iris is of only secondary importance, but it is indicated when there is a serous accumulation behind the iris. Schön has said that exaggerated efforts of accommodation constitute an efficient cause of glaucoma, and it is well, therefore, to avoid all excess in this direction. Absolute glaucoma demands enucleation, both on account of the pain and because of the possible existence of tumors of the choroid. Enucleation is preferable to exenteration.

Dr. Schön, of Leipzig, presented a communication on

ACCOMMODATIVE EXCAVATION SIMULATING SIMPLE GLAUCOMA.

He had observed several cases, especially in hypermetropes, in which there was an excavation of the papilla resembling that of simple glaucoma.

Dr. Straub, of Utrecht, read a paper on

THE CHOROID CONSIDERED AS AN ELASTIC ORGAN,

in the normal and the diseased eye. The muscular tissue throughout the body is that which possesses the greatest elasticity, and it is indispensable in resisting tension. The muscular organ in the eye is the choroid, and it is this, and not the sclerotic, that sustains the intra-ocular pressure. When the elasticity of this membrane is destroyed, a venous stasis takes place, the fluids of the eye increase in volume, the zonula is projected forward, and there is a tendency to glaucoma.

Dr. Wahlfors, of Helsingfors, read a paper on the

MEASUREMENT OF INTRA-OCULAR PRESSURE.

He said that the tension increased when there was blood stasis.

These papers were followed by a general

DISCUSSION ON GLAUCOMA.

Dr. de Wecker was opposed to the use of the lance-knife in sclerotomy. He preferred a straight cataract knife, and had never seen prolapse of the iris follow the operation.

Dr. Pflüger, of Berne, said that glaucoma might be of syphilitic origin. He advised against iridectomy in this disease.

Dr. Leber, of Göttingen, had found an obstruction, probably inflammatory in character, in the angle of infiltration in a number of enucleated glaucomatous eyes which he had examined.

Dr. Galezowski, of Paris, advised posterior sclerotomy by means of two incisions extending to the choroid. These incisions, made externally above and below, are easy of execution and without danger.

Dr. Samelsohn, of Cologne, opposed sclerotomy, and did not believe that it was of any value.

Dr. Schmidt agreed with the previous speaker concerning the inutility of sclerotomy. He had seen a case of syphilitic glaucoma cured by specific medication.

Dr. Hess, of Prague, presented a communication on

THE ARTIFICIAL PRODUCTION OF CATARACT WITHOUT RUPTURE OF THE CAPSULE.

He had caused cataract artificially by means of electricity from the discharge of a Leyden jar.

Dr. Bernheimer, of Heidelberg, read a paper on

THE OPTIC CHIASM IN MAN.

He had observed the presence of direct and of crossed fasciculi, but the fibres of the two mingle with each other.

Dr. Schmidt-Rimpler, of Marburg, reported a case of

PARTIAL OPTIC ATROPHY IN CEREBRAL HEMIANOPSIA.

Dr. Howe, of Buffalo, read a paper on

THE INFLUENCE OF FLIES IN THE PRODUCTION OF EGYPTIAN OPHTHALMIA.

This is not a granular ophthalmia, such as is generally described, but a periodical suppurative conjunctivitis. The disease is transmitted through the medium of common house flies, as is shown by the facts that the epidemic appears and disappears simultaneously with the flies; that the disease is most prevalent in the cities, where the flies are most numerous, and is absent in the desert, where the flies are not found; and that cultures demonstrate the presence of the pathogenic microbes on the legs of the insects.

Saturday, August 11th—Fourth Day.

Dr. Leber, of Göttingen, read a paper on

THE IMPORTANCE OF BACTERIOLOGY IN OPHTHALMOLOGY.

Most inflammations of the eye have a microbial origin, and owing to its exposed situation the organ is very accessible to micro-organisms coming from without. But it also, though more rarely, suffers from microbial infection from within. Sympathetic ophthalmia is probably due to the presence of micro-organisms which are carried along the lymphatic spaces. To this group of infections belongs also infection of the orbit and of the cavernous sinus following enucleation. Foreign bodies in the eye, copper especially, cause purulent inflammation without the intervention of microbes.

Dr. Sattler, of Prague, said that there are three principal groups of

MYCOTIC AFFECTIONS OF THE EYE.

The first group comprises diseases in which the infective germs exercise their injurious effect through an intact surface; these are: Acute purulent conjunctivitis, trachoma, diphtheria of the conjunctiva, and acute infectious catarrh. In the second group a solution of continuity is necessary for the entrance and development of the germs; these are: Primary syphilitic chancre of the conjunctiva, tuberculosis of the conjunctiva, and suppurative processes. The third group embraces those diseases in which the microbes gain entrance through the blood and lymphatic channels.

Dr. Chibret, of Clermont-Ferrand, read a paper on the use of

CYANIDE OF MERCURY IN OCULAR ANTISEPSIS.

The instruments should be placed in a one per cent. solution of this substance five minutes before they are to be used. The eyes should be bathed in a 1 to 1,500 solution of the same drug.

Dr. Deutschmann did not regard sympathetic ophthalmia as due to any specific infection, and believed that any of the microbes of suppuration might excite it.

Dr. Knapp thought there was no danger of ophthalmia after traumatisms, provided the instruments were thoroughly sterilized, and all antiseptic precautions were observed.

Dr. Mazza Andrea, of Geneva, reported the results of some experiments on animals to determine the

MODE OF ORIGIN OF SYMPATHETIC OPHTHALMIA.

He had injected staphylococcus into the vitreous body, and had never found the micro-organisms passing beyond the papilla. The only cases in which they were found in the optic nerve were when they had been injected directly into it.

Dr. Dor, of Lyons, related a case of

SYMMETRICAL COLOBOMA OF THE TWO UPPER EYELIDS.

He rejected the theory of amniotic bands in the production of the affection, and thought it was due rather to an arrest of development.

Dr. Knapp, of New York, read a paper on the

NOTATION OF THE MERIDIANS IN THE EMPLOYMENT OF CYLINDRICAL GLASSES.

He described the French, American, and Anglo-German systems of notation, expressing a preference for the latter.

Dr. Landolt proposed to extend the system of notation of spherical and cylindrical glasses to prismatic glasses as well.

Dr. Haab, of Zurich, read a paper on

AFFECTIONS OF THE MACULA LUTEA,

describing the traumatic, anæmic, and senile forms of maculitis.

It was voted to hold the next Congress in Edinburgh. Then, after a few words by the President, congratulating the members on the work done, and thanking the citizens of Heidelberg for all the favors which they had extended to the visiting physicians, the Congress was adjourned.

THE MEDICO-CHIRURGICAL SOCIETY OF GERMAN PHYSICIANS.

Stated Meeting, October 1, 1888.

L. Weber, M.D., President, in the Chair.

In opening the meeting the Chairman extended a hearty welcome to the honored guest of the evening, Professor v. Esmarch, of Kiel, who not only had consented to be present at this session, but had kindly agreed to read a paper on a very interesting topic.

Dr. W. Freudenthal read a paper

ON THE ETIOLOGY OF HERNIA,

in which he claimed that there was a distinct causal relation between the development of hernia and naso-pharyngeal disease, especially of the catarrhal variety. He had collected trustworthy statistics from many sources, which all tended to show that the frequency of hernia corresponded with that of nasal affections. He did not believe that nasal reflex had anything to do with the establishment of rupture, but gave a mechanical explanation of its origin, viz., augmented force of intra-abdominal pressure and the increased frequency of its employment.

America he alluded to as pre-eminently the land of nasal catarrhs, and America was also the country where hernia was quite common. In this particular he took issue with certain contrary statements that had appeared in The Medical Record, tending to show that hernia was less frequent here than in other countries.

Professor F. von Esmarch was then invited to deliver his address. He prefaced his remarks by paying a graceful compliment to American hospitality, which in his travels in this country had everywhere been prominently brought home to him. He also apologized for not having prepared an elaborate paper for this occasion, and begged the members to accept in place thereof some

CLINICAL REMARKS ON ARTICULAR NEUROSES.

He commenced by saying that articular neuroses, like all nervous affections, were observed in America in large numbers. But in Europe, also, these affections were by no means very rare.

Sir Benjamin Brodie had well described them under the name of hysterical affections of the joints. Stromeyer had also classed them with the group of disturbances comprised under the name of hysteria. They had often been spoken of as neuralgia of joints. He preferred the more general term of neurosis, for neuralgic pain was not always a prominent feature of these cases. He narrated

A VERY TYPICAL CASE

of this kind which had come under his observation at Kiel, in the time of Stromeyer. A woman applied to the latter at his clinic, with a swelling of the leg that resembled ordinary tumor albus. She related a story of suffering extending over years, and as she was growing constantly worse, she clamored for removal of the offending member by amputation. Stromeyer, however, feeling convinced that the affection was a neurosis, through moral suasion induced the woman to rise and walk about, thus using a leg which had before been apparently totally useless. A cure speedily followed. This case, happening many years ago, had greatly impressed him, and being on the look-out for such cases, he had come to observe a large number of them. He had collected and described many of these in his monograph on the subject; and since writing that little book he had seen a still larger number of affections of this kind.

Regarding the symptomatology of articular neurosis, he stated that a great variety of signs were observed. There might be contractures, scoliosis, dropsy of the joints, puffiness that came and went, urticaria-like wheals over the painful joints, and other symptoms simulating entirely different maladies. Yet the underlying condition was a pure neurosis. The affection was frequently seen in neurasthenics, a term which America had given to the medical world, and men were by no means exempt from the disease.

The immediate exciting cause was often a traumatism. A patient would fall, or be struck, and the ensuing pain and swelling would not disappear in the natural way after a lapse of time. Rest and antiphlogistic treatment were apt to be advised by the attending physician; but the patient would go on from bad to worse. Other physicians, mistaking the true nature of the disorder, would employ counter-irritants, hot baths, anti-rheumatics, and a variety of things, which generally had little or no effect. It was only when the neurotic character of the disease was made out that a well-directed moral and psychic treatment would promptly effect a recovery.

Articular neuroses were often seen which depended upon uterine disease, and their origin was, of course, like that of all reflex disturbances of the nervous system. He remembered a very striking case of this kind, where the patient was apparently suffering from morbus coxarius, a diagnosis to that effect having been made by a physician.

In a general way, it might be said that

THE DIAGNOSIS WAS OFTEN QUITE DIFFICULT

to make, more particularly in the early history of these cases. Articular neuroses often looked like true inflammatory affections, and might easily mislead the unwary. On the other hand, those who saw many cases belonging to this category, were in danger of going too far in an opposite direction, *i.e.*, that of regarding other articular diseases as neurotic in origin. He himself had to confess to errors of that kind.

There was generally, however,

A NOTICEABLE DISPROPORTION BETWEEN SUBJECTIVE SYMPTOMS AND OBJECTIVE SIGNS.

One or more circumscribed areas of extreme tenderness were often observed. The slightest touch would produce apparent agonies in the patient. The diagnosis was greatly aided ex juvantibus et nocentibus. If a patient with supposed rheumatism, for example, was only made worse by rational anti-rheumatic treatment—if she had gone the rounds of the doctors and came to you with the history that everything made her worse—a strong presumption in favor of articular neurosis existed.

The facial expression of these patients was often peculiar, like that of many belonging to the neurotic type. The case that he had already alluded to, of a lady who applied to Stromeyer for amputation of the leg, was recognized by Esmarch twenty years later, merely from the peculiarity of her facial expression.

The treatment of these disorders was largely of a psychic kind. Moral suasion, properly employed, was very effective. The patient must be encouraged and made hopeful. It was sometimes sufficient to tell bedridden patients to rise and walk, and insist on their doing so. A typical case was narrated in illustration of this statement.

He was aware that serious operations, such as exsections of joints and amputations, had been done in cases of articular neurosis. The speaker mentioned the case of a girl, in whom he had laid open the hip-joint, although he had felt almost certain that the disease was neurotic. The patient had symptoms of apparent coxitis, that yielded to treatment by extension, the application of cold, etc. When put on her legs again, the former symptoms quickly returned and a marked febrile movement developed. It was finally decided to lay open the hip-joint, and all the structures were found perfectly healthy. The operation was done under the usual antiseptic precautions, and the result was satisfactory, for the neurosis was cured. The speaker had found that exercise in place of rest was very useful in these conditions. Warm baths generally did harm, but cold bathing or sponging, or the cold douche, were very useful. Sea-bathing often proved highly beneficial. Concerning the employment of drugs or electricity the speaker gave no information.

Dr. Detmold said that he recalled a typical case of elbow-joint neurosis. The patient appeared to have about her a

SENSITIVE ATMOSPHERE.

When several inches away from the joint, objects or the physician's hand would cause her to scream with pain.

Dr. v. Esmarch mentioned a characteristic and familiar phenomenon in this connection. A patient with a tender spot, the slightest pressure upon which produced intense pain, should be engaged in conversation. By thus distracting her attention the tender spot might be firmly pressed without eliciting any manifestation of pain. But this would immediately return if the patient became aware of the fact that her tender spot was being pressed.

Dr. Lange stated that articular neuroses were frequently observed in this city, and their true nature was often not recognized. He had had occasion several times to correct the diagnosis of other physicians, and by radically changing treatment and giving a different prognosis to bring about recoveries where others had failed. He would say also that pathological changes might be present, and yet the case be one of neurosis. Indeed, long-standing cases often did show articular atrophy due to the inaction of the joint. The surroundings of a patient and the circumstances attending the development of the disease often afforded a clue to the diagnosis. He had observed patients that seemed to have two souls, as it were, the one suffering and the other eagerly watching the ordeal of pain. In young men, especially those addicted to masturbation, these neuroses were often seen. He instanced a case of this kind where boxing the ears had led to recovery. These neuroses assumed a great variety of disguises. He recalled a case of apparent genu valgum that had come under his observation.

Business men who had troubles and anxieties were very apt to suffer from these affections. A condition which gave rise to mistakes was articular syphilis, and it was often difficult to make a correct diagnosis.

Dr. v. Esmarch remarked that men sometimes complained of a feeling of extreme weakness of the limbs, rather than pain. He described the case of a merchant who met with a sudden reverse of fortune and who had this feeling of inexpressible weakness. On the return of affluence he promptly recovered. He also took occasion to point out, in this connection, how important it was to save such patients from sympathizing friends and relatives, a point that had been very properly emphasized by Weir-Mitchell.

Painless Tooth Extraction.—Drs. Hénoque and Frédel, in a communication made to the Biological Society of Paris, state that the extraction of a tooth may be rendered painless by spraying the neighborhood of the external ear with ether. The anæsthesia of the trigeminus so produced extends to the dental nerves, and thus renders the production of general anæsthesia needless.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, June 27, 1888.

Frank Ferguson, M.D., Vice-President, in the Chair.

Dr. J. J. Griffiths presented a specimen, on behalf of a candidate, showing the engagement of the omentum in the lateral perforations of a glass drainage-tube.

Dr. H. J. Boldt presented a specimen of

ABSCESS OF THE UTERUS, PUERPERAL PYO-SALPINX, AND INTRA-PERITONEAL ABSCESS.

The patient, J. G——, aged twenty-two, married for five years, had been referred to him by Dr. L. Weiss. She had had three children and no miscarriages. The last child had been born four weeks before the speaker saw the case. The labor was normal. Two hours after delivery the woman had a chill, which was followed by a high temperature and profuse sweating. The axillary temperature varied from 103° to 105° F. There was constant pain over the lower portion of the abdomen, the uterus was large and flabby, and on either side of it was felt a fluctuating movable mass, supposed to be the distended Fallopian tube. The case was thought to be one of septic salpingitis following delivery, a diagnosis which was strengthened by the facies of the patient.

Abdominal section was decided upon, but the patient died in collapse a few hours later. The operation was very difficult on account of the very dense adhesions which had partly been diagnosed before operation. On the right side the tumor felt proved to be the distended Fallopian tube, which ruptured while separating the adhesions, discharging the purulent contents into the abdomen. On the left side, however, the tumor which was thought to be the distended tube proved itself to be an encapsulated intra-peritoneal abscess, which also burst during the operation; the Fallopian tube, although inflamed, and in consequence considerably enlarged, presented nothing unusual. The ovary was very intimately attached to the uterus, so that removal would have been impossible without injury to the uterus itself. Drainage was used.

At the autopsy the remaining tube was found firmly occluded about three-fourths of an inch from its uterine extremity. In cutting through the anterior uterine wall, an abscess was found in the substance of the muscular structure, which contained about two drachms of pus. The cavity of the abscess had the shape of a round canal, traversing nearly the whole breadth of the uterus, and situated in the upper half of the body; it was entirely shut off from connection with any other structure, and was regarded as the result of an infarction by the speaker. The diameter of the abscess canal was three eighths of an inch. The cavity of the uterus measured three and one-half inches. The large size and flabby condition of the uterus, the speaker regarded as partly due to the abscess in the muscularis.

Dr. Ferguson had recently seen an abscess in the wall of the large intestine, occurring as the result of occlusion of the artery by an embolus. The abscess had ruptured into the lumen of the gut, but this was probably the result of manipulation post mortem. The case was one of malignant endocarditis.

Dr. H. P. Loomis presented a specimen of

PATENT FORAMEN OVALE,

in a man fifty-three years of age. The man had always been troubled with shortness of breath and cyanosis. He said that his mother had told him that he was a "blue baby." He had lived in Switzerland until ten years ago, when he came to this country. Since coming here he had been much worse and had been unable to work. Physical examination showed a dilated heart with an indistinct murmur, which was later resolved into a mitral regurgitant.

At the autopsy there was found an infarction in the lower lobe of each lung, one of which was old, the other recent. The heart weighed a pound and a half, was flabby, dilated, and had very thin walls. The interauricular septum was thinned, and at its lower portion was a perforation admitting a quill, which was, however, closed by a valvular flap of tissue which seemed to be competent to prevent the passage of blood. The kidneys presented a classical picture of infarctions, some comparatively recent, others older.

Dr. Loomis also presented other specimens showing

MASTOID DISEASE, PACHYMENINGITIS, AND MULTIPLE VISCERAL ABSCESSES.

Owing to the patient's limited command of English it was impossible to obtain a satisfactory clinical history. It was, however, learned that he had suffered for about a week from intense hemicrania accompanied with a discharge of pus from one ear. Soon after the pain ceased the left arm and leg became cold, and then gangrene appeared in the hand and foot.

At the autopsy the mastoid cells were opened and were found to contain a few drops of thick pus. There was pachymeningitis on the same side, and suppurative thrombi were seen in the lateral sinus. The axillary artery was occluded at its point of junction with the brachial, and there was suppuration along the course of the arteries. Pyæmic abscesses were found in the lungs and spleen.

Dr. Ferguson, referring to the first specimen presented, said that he had seen a number of cases of patent foramen ovale in adults in which there had been no heart symptoms during life. In every instance there was a flap of tissue present serving as a valve. He thought the condition of the heart-walls, which were thin, flabby, and fatty, was sufficient to account for the later symptoms of dyspnœa and cyanosis in this case.

Dr. Ferguson then exhibited a microscopical slide of a section through the mucosa of the stomach of a man who had died of pernicious fever, showing the

MALARIAL PIGMENT.

The vessels were filled with the pigment, looking as if they had been artificially injected. The man had been brought to the hospital in a partially comatose condition, and never rallied sufficiently to give a clear account of his illness. All that could be learned was that he had had a bilious attack for three days, and was found on the street in a nearly unconscious state. He gradually grew worse, the temperature toward the end being 106°, and died three days after admission. The diagnosis was made *intra vitam* by the examination of the blood. A large amount of pigment was found in all the organs, but especially in the brain and stomach.

The Society then went into executive session.

The Late Dr. Agnew's Charities.—In his eloquent eulogy on Dr. Agnew, Dr. Thomas spoke of his constant generosity to the poor and to all kinds of charitable enterprises. He adds: "After thirty years of brilliant professional success, of uninterrupted health, of industry, of frugality, beyond making simple provision for the needs of those immediately dependent upon his labors, he died comparatively poor in this world's goods. Is the reason far to seek? In revealing this I violate no confidence, for this is the climax of his fame, the cap-sheaf of his career, the crowning glory of his life, to which his children point with pride! Had it been otherwise, a want of symmetry would have disturbed the perfect rotundity of his career. As it is, the fair proportions of a beautiful record are left free from blemish and without spot. His income was immense, and he steadily invested it; some will say wisely; for he put it out of reach of moth, of rust, and of thieves."

OUR PARIS LETTER.

(From our Special Correspondent.)

CHOLERA INOCULATION—HYDROFLUORIC ACID IN TUBERCULOSIS—CONGENITAL EPISTAXIS—SACCHARIN IN ALIMENTARY PRODUCTS.

PARIS, August 31, 1888.

A RATHER sensational subject, that has been occupying the public mind both in and out of the profession, is the reputed discovery of a cure for cholera by inoculation. At the meeting of the Academy of Sciences of August 20th, M. Pasteur read a communication for Dr. Gamaleia, of Odessa, in which the author gives an account of the procedure he had adopted, which is similar to that practised by M. Pasteur for hydrophobia. Dr. Gamaleia had studied M. Pasteur's method in Paris, and his experiments with the choleraic virus upon animals have, according to him, proved successful. Dr. Gamaleia's method is based on his discovery that pigeons inoculated with the blood of guinea-pigs which have been inoculated with cholera virus die from "dry cholera," with detachment of the intestinal epithelium. That which is still more important is that the microbe appears also in the blood of pigeons which have succumbed. When the virus has thus passed through the pigeon, it acquires such intensity, that one or two drops will kill pigeons in from eight to twelve hours, and even destroy guinea-pigs. But when a pigeon was inoculated with the uncultured virus in the breast and in the abdomen, it became refractory to the cultivated virus of the highest intensity of virulence. If the culture-broth be heated to 120° C., for twenty minutes, to destroy with certainty all the microbes which it contains, it is observed that the heating had left a very active substance in the sterilized culture, which contains a toxic substance which determines the characteristic phenomena in the animals experimented on. M. Pasteur, who evidently concurs in the value of the results obtained by Dr. Gamaleia, hopes that whole populations may be saved by this method from the dire disease, and referred Dr. Gamaleia's communication to the committee which has a prize of 100,000 francs at its disposal for a cure for cholera. Dr. Gamaleia has expressed his readiness to repeat the experiments at Paris, in presence of a committee of the Academy of Sciences, and to try on himself the inoffensive and, what he considers, sufficient dose for human inoculation. He stated that he was also ready to undertake a journey into any countries where cholera prevails to prove the efficacy of his method. M. Pasteur readily accepted the offer, and it has been arranged that the experiments should be carried on in his laboratory in November next. It is to be hoped that these experiments will prove more trustworthy and effectual than were the inoculations with which a few years ago Dr. Ferran's name was associated. It will be remembered that from the investigations pursued in Egypt by the French Cholera Commission, one of its members, the lamented Dr. Thuillier, fell a victim to the disease, notwithstanding the anti-choleraic inoculation which was practised on him.

Drs. Grancher and Chautard have instituted a series of experiments on the action of hydrofluoric acid in tuberculosis. These experiments, practised on rabbits inoculated and with variable degrees of dilution, have given appreciable results with only a certain degree of concentration—inhalations at sixty and eighty per cent. The following are the conclusions of the authors as published in the *Bulletin Medical:* "It would appear that these experiments do not justify all the hopes that observations of favorable cases in the human species had given rise to, unless that, by an indirect action on the secretions and on nutrition, the vapors of hydrofluoric acid favorably influence the progress of tuberculosis. We do not believe that one can legitimately hope to reach and destroy in the depths of the economy, by the vapors of hydrofluoric acid, the tubercle bacillus, which these same vapors attenuate, but do not kill in 'vitro,' after a contact prolonged for more than four hours." But, add the authors, all attempts to combat the agent of pulmonary phthisis are legitimate, and the vapors of hydrofluoric acid, which are well tolerated by the greater number of patients, are, at least, a means of attenuation, if not of the destruction, of the tubercle bacillus.

In a work just published by Dr. Yoal, of Mont Dore, entitled "Genital Epistaxis," the author studies the etiology of spontaneous epistaxis, idiopathic of adults, which are ordinarily put to the account of plethora or of anæmia. Without denying the intervention of a diathetic state (rheumatism, gout), Dr. Yoal thinks that in certain cases bleedings from the nose are due to excitement of the genital organs, excitement either physiological showing itself at the age of puberty, or pathological and resulting from vicious habits. In support of this view, the author shows by numerous citations that from the most ancient times it was admitted that there exists a veritable sympathy, an intimate correlation, between the apparatus of reproduction and that of olfaction. The recent works of Bigelow, Voltolini, Kiesselback, John Mac Kensie, etc., on the structure of the pituitary membrane, and the presence of erectile tissue in the nasal fossæ, have conduced to the necessity of attributing an important rôle, in the mechanism of the production of these hemorrhages, to the exaggerated turgescence of the cavernous bodies. Starting from these principles, and supported by his own personal observations, Dr. Yoal divides the different forms of epistaxis into five groups: 1. Traumatic and ulcerative. 2. Dyscrasic. 3. Mechanical. 4. Vaso-motor. 5. There exists an intimate relation, a veritable sympathy, between the nose and the apparatus of reproduction.

At its meeting of August 13th the Council of Public Hygiene approved the following conclusions of a report submitted by Drs. Brouardel, Pouchet, and Ogier, on the employment of saccharin in alimentary products in a hygienic point of view: 1. Saccharin is not an aliment and cannot replace sugar. 2. The employment in alimentation of saccharin or of saccharinated preparations, suspend or retard the transformation of amylaceous or albuminous substances in the digestive tube. 3. These preparations have, therefore, for effect to profoundly trouble the digestive functions. They are of a nature to multiply the number of affections designated under the name of dyspepsia. 4. The employment of saccharin is too recent for the consequences of an alimentation in which would enter daily a certain quantity of saccharin to be all determined, but it is for the present established that its employment has a pernicious influence on digestion, and the reporters feel justified in concluding that saccharin and its divers preparations should be proscribed from alimentation.

Dr. H. Frémy is charged with a mission to the United States for the purpose of visiting the public and private establishments of that country devoted to the treatment of tuberculosis.

MIDDLE-EAR DISEASE AND ROOSA'S INHALER.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: If you will kindly allow me a few lines of your valuable space I will reply to Dr. H. P. Allen's criticisms on an article published in your issue of August 11th, entitled "Four cases of Acute Inflammation of the Middle Ear from the Use of Roosa's Bulb Nasal Inhaler." The title of the article was incorrectly published. The original manuscript reads "From the *Abuse* of Roosa's Bulb Nasal Inhaler." Dr. Allen probably inferred that I wished to cast reflection upon the little instrument, such was not the case however.

I have been associated with Dr. Roosa in the Manhattan Eye and Ear Hospital for the past five years, personally attached to his clinic for three of those years. It was he who taught me the use of the inhaler, and I thoroughly know its uses and appreciate its merits.

In the four cases referred to by Dr. Allen, the nasopharynx was cleansed with a Dobell spray previous to inflation, as is my custom always to do. I make no applications to the nares or pharynx before thoroughly cleansing the passages. Neither do I attempt to blow the fetid secretions of the pharynx into the orifices of the Eustachian tubes, as one must do if he does not cleanse the passages first.

I have inflated hundreds of ears after this manner and never had an accident yet. As for the iron and glycerine, the application was made so far back it could not possibly have reached the Eustachian orifices.

I do not think Dr. Allen is at all conversant with the inhabitants of our Croton water. I would respectfully call his attention to reports made to the New York County Medical Society and articles by Dr. Prudden.

The paper in question was discussed at the New York Academy of Medicine by Knapp, Webster, Corning, Moore, Weeks, and Andrews, none of whom gave any such theory as that advanced by Dr. Allen, but, on the contrary, some were kind enough to say that the conclusions were so well drawn there could be no doubt as to the cause, and I would dislike very much to know that others doubted the theory. If physicians would report more of their casualties in the practice of medicine, the rising profession would have less cause to learn things from sad experience.

FRANK W. RING, M.D.

New Instruments.

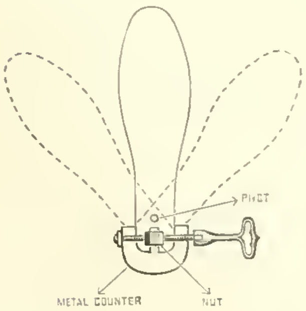
IMPROVED FORM OF CLUB-FOOT SHOE.

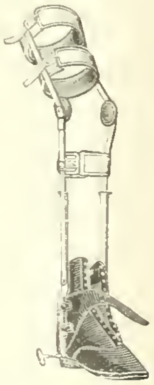
By THOMAS G. ALLEN, M.D.,

BUFFALO, N. Y.

THIS shoe is designed to correct the milder cases of talipes without operation; to be worn immediately following the division of tendons and fascia, or when the plaster-of-Paris dressing is removed. The arrangement secures to the foot as nearly a normal position as possible.

I was led to the construction of a new form from the inability of the ordinary club-foot shoe to hold the foot without so much false motion, after it had been placed in a corrected position; and from a desire to improve upon the unsightly appearance of a shoe with an open toe-end, divided uppers, metal pieces on the outside, springs, rubber tubing, chains, and such burdensome apparatus so embarrassing to the wearer.





A laced shoe of calf-skin is made over a straight last according to the measure of the foot. Instead of the usual metal piece at the metatarso-phalangeal joint of the great toe, I use a piece of sole leather or copper on the *inside* of the shoe. The leather sole is divided crosswise, about one-fourth of an inch back of the anterior part of the heel, and this joint is covered by the last layer of the heel.

Abduction and adduction of the sole and foot is produced by turning the key just above the heel. A glance at the diagram will better explain the mechanism.

An inner sole of sheet-iron has the heel end slotted so as to hold a nut. In front of this slot is a pivot upon which the lateral movement is obtained by the travelling of the nut against the side of the slot when the screw is turned. Any amount of lateral motion can be accomplished by this means.

To lessen the medio-tarsal outward rotation, I have used the strap shown in the cut, and have had the leather-sole bevelled from one-eighth to one-half an inch in thickness. In cases of varus this assists in breaking down the high arch of the foot.

The screw movement for the lateral motion occurred to me some two years ago, but as far as I am aware, to Mr. Henry Herrmann, a manufacturer of surgical instruments of Buffalo, N. Y., belongs the credit of first using this mechanical device. And I would here thank that gentleman for his able assistance.

I do not claim that this shoe answers for all cases of such deformity, the judgment of the surgeon is to be governed by the character of his case. But after repeated trials during the past two years, I have arrived at satisfactory results, and do claim for my contrivance the following advantages: 1. Neatness; not unsightly. 2. Screw movement for lateral motion. 3. Metatarso-phalangeal piece placed inside instead of outside. 4. Upper leathers not divided, or open. 5. Sole divided within the heel. 6. Shoe vise-like in action. 7. Bevel of sole and heel in cases of varus, to restrain medio-tarsal rotation. 8. A perfect club-foot shoe, appearing as an ordinary laced shoe.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 23 to September 29, 1888.

STERNBERG, GEORGE M., Major and Surgeon. By direction of the President, will proceed to Decatur, Ala., and to such other points in the infected districts of the Southern States as he may deem necessary, to continue his scientific investigations of yellow fever. Par. 8, S. O. 224, A. G. O., Washington, September 26, 1888.

Under authority from Headquarters of the Army, A. G. O., dated September 22, 1888, Major CHARLES B. THROCKMORTON and Batteries K and M, Second Artillery, comprising the garrison of Jackson Barracks, New Orleans, La., will proceed at once, by sea, to New York Harbor, and upon arrival there will take post at Fort Wadsworth, New York Harbor. A small guard of enlisted men will be left at Jackson Barracks. Major JOHN W. WILLIAMS, Surgeon, will accompany the troops to New York Harbor. Major HARVEY E. BROWN, Surgeon, will remain at Jackson Barracks. Par. 12, S. O. 202, Headquarters Division of the Atlantic, Governor's Island, New York City, September 26, 1888.

WHITE, ROBERT H., Major and Surgeon. Granted leave of absence for one month, with permission to apply for an extension for one month. Par. 7, S. O. 199, Headquarters Division of the Atlantic, Governor's Island, New York City, September 22, 1888.

WILSON, GEORGE F., Captain and Assistant Surgeon. By direction of the Acting Secretary of War, granted leave of absence to include May 3, 1889. Par. 14, S. O. 223, A. G. O., September 25, 1888.

WOODRUFF, EZRA, Captain and Assistant Surgeon. By direction of the Acting Secretary of War, granted leave of absence for six months, on surgeon's certificate of disability, with permission to leave the Division of the Missouri. Par. 5, S. O. 223, A. G. O., September 25, 1888.

MATTHEWS, WASHINGTON, Captain and Assistant Surgeon. By direction of the Acting Secretary of War, detailed as a member of the Army Medical Examining Board appointed to meet in New York City, October 1, 1888, by special orders No. 203, September 1, 1888, from this office, vice Major George M. Sternberg, Surgeon, hereby relieved from his detail as a member of the Board. Par. 3, S. O. 224, A. G. O., Washington, September 26, 1888.

HOFF, J. VAN R., Captain and Assistant Surgeon, upon the recommendation of Captain Daniel Weisel, Senior Medical Officer, Camp of Instruction of the 5th Cavalry, assigned in charge of active operations of the hospital corps in that camp. Par. 2, S. O. 121, Headquarters Department of the Missouri, Fort Leavenworth, Kan., September 22, 1888.

WILSON, GEORGE F., Captain and Assistant Surgeon. Resignation accepted by the President, to take effect May 31, 1889. Par. 15, S. O. 223, A. G. O., September 25, 1888.

By direction of the Acting Secretary of War, the following named officers of the Medical Department will report in person, on October 9, 1888, to the President of the Army Medical Examining Board, Army Building, New York City, for examination for promotion: Captain BENJAMIN MUNDAY, Assistant Surgeon; Captain WILLIAM O. OWEN, JR., Assistant Surgeon. Upon the completion of their examination to rejoin their stations. Par. 15, S. O. 225, A. G. O., Washington, September 27, 1888.

Official List of Changes in the Medical Corps of the United States Navy for the week ending September 29, 1888.

HUDSON, ADRIAN, Medical Inspector. Ordered for examination preliminary to promotion to Medical Director.

BATES, NEWTON L., Medical Inspector. Ordered for examination preliminary to promotion to Medical Director.

COOKE, GEORGE H., Surgeon. Ordered for examination preliminary to promotion as Medical Inspector.

BRADLEY, MICHAEL, Medical Inspector. Ordered as member of Naval Examining Board.

WELLS, HENRY M., Medical Inspector. Relieved from duty as member of Naval Examining Board.

SIMONS, MANLY H., Surgeon. Ordered to Widows Island Naval Hospital.

HEFFENGER, A. C., Passed Assistant Surgeon. Detached from Naval Hospital, Widows Island, and wait orders.

SAM JONES ON "FAITH CURE" AND "CHRISTIAN SCIENCE."—"I'll tell you where this faith cure comes in. There's an old brother and a sister who have been taking all the nasty, quack patent medicines on the market for the last ten years. Somebody comes along and prays over 'em, and they quit using the patent medicines, and they are well again. They say it was faith that cured. It was faith. It was faith which caused them to quit taking old patent nostrums, which cured them. I don't say I belong to the Christian Science crowd, or anything of that sort; but I thank God that by the side of my sick wife I may kneel down and pray that the remedies given by the physician may prove effective. I don't pray over the supernatural. I pray over the pill."

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 29, 1888:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	74	22
Scarlet fever	72	14
Cerebro-spinal meningitis	0	1
Measles	53	7
Diphtheria	60	17
Small-pox	0	0
Yellow fever	0	0
Cholera	0	0

ILLEGITIMACY IN MASSACHUSETTS.—The last report of the Massachusetts State Board of Health makes a bad showing for the morality of the Bay State. The percentage of illegitimacy has steadily increased in the last ten years from 1.12 to 2.03 per thousand in 1886. In the distribution the factory districts were found to claim more than their due proportion.—*Sanitary News.*

SCULPTORS' CLAY IN THE TREATMENT OF MASTITIS.—Dr. E. L. Maïzel mentions in the *Vrach* (No. 21) that he has for some time employed modelling clay as an application in mastitis, with excellent results. The idea was obtained from Dr. S. Lukashevich, who employed white modelling clay in epididymitis. Dr. Maïzel has made use of it in twelve cases—seven of parenchymatous inflammation, of which only three suppurated; and five of phlegmonous inflammation, of which only one went on to form an abscess. The pain was rapidly alleviated and the fever diminished by this treatment, which, if commenced sufficiently early, appeared to cause the inflammatory process to terminate in resolution without the formation of pus. When abscesses had formed and broken, the wound rapidly healed, and the indurated lobules returned to their normal condition without suppurating, the clay proving a much less troublesome treatment than Kiwisch's plan of starched bandages, and much less painful than the application of collodion, as recommended by Latour and Sprengel, being at the same time quite as satisfactory in its results. This method is especially suitable for country practice, as white modelling clay is a very common and cheap substance, and patients take to the treatment very kindly, the application being always grateful to them. The capacity for heat possessed by clay being considerable, it answers the purpose of ice-bags or cold compresses, and is greatly preferred to them by the patients. The method of application is simple enough. The breast is first washed with a sponge and a piece of soft gauze applied to it. Another piece of gauze is then cut to the proper size, an aperture being made for the nipple, and an even layer of well-mixed clay, free from lumps, spread over it. This is then applied to the breast over the first piece of gauze, and secured by a bandage passing over the shoulder of the opposite side. The dressing is renewed night and morning. This kind of treatment is also applicable in distressing fulness of the breasts, when for any reason the patient cannot suckle the child. The secretion is arrested and the fulness and tenderness often disappear in the course of twenty-four hours.—*The Lancet.*

A SAD ACCIDENT.—One of the Western dailies reports the case of a man who, in falling a distance of fifteen feet broke four of his ribs, "one of which protruded through the flesh into the placenta."

CHLOROBORATE OF SODIUM, which has been brought forward as a new and efficient antiseptic, is said to be a simple mixture of borax, boracic acid, and chloride of sodium.

Barium and Digitalis.—Salts of barium, though they have been occasionally employed therapeutically, have never been very generally recognized as really useful therapeutic agents, either in this country or abroad, partly, perhaps, from a want from knowledge as to their effects both on physiological and pathological conditions. This knowledge Dr. A. Bary, of Dorpat, has recently endeavored to supply, to some extent at least, by making a large number of investigations on the action of barium salts on animals, as well as by collecting recorded cases of the therapeutical employment of the drug or its accidental effects as a toxic agent in the human subject. The salt he mainly used was the chloride, a substance with which every one is perfectly familiar in the laboratory, if not in the dispensary. The chief action of barium appears to be on the heart, showing great similarity to the action of digitalis, and somewhat less to that of physostigmin. Thus it was found, by experiments on frogs, that in small doses barium increased the action of the heart muscle, and in large doses set up peristaltic movements, arresting the heart finally in systole, this arrest in systole being a tetanic spasm of the heart muscle, and being capable of being brought to an end by agents which paralyze muscles and by mechanical distention by fluid pressure, but not by the electric current or by atropin. In very acute poisoning, either by large doses or by the direct application of the chloride of barium to the heart, the frog was found, even after the heart had stopped, to be capable of jumping. Again, the isolated apex was caused to beat by barium, being finally arrested in systole. The arrest caused by muscarin and chloral was brought to an end by using this salt. It was found that arrest in diastole could not be produced under its action by stimulation of the vagus or of the sinus venosus. The effects of barium on the arrest caused by muscarin, and the want of result from irritating the vagus, were found not to be due to any paralyzing action of the salt on the vagus. The foregoing effects are as nearly as possible identical with those produced by digitalis, differing also only in a slight degree from those of physostigmin. In warm-blooded animals barium in small doses slows the pulse independently of the inhibitory apparatus; in large doses it first accelerates the pulse, probably by stimulating the accelerating nerve, and finally slows it, in consequence of weakness of the heart. The blood-pressure is greatly increased by barium. Like pilocarpin, barium increases in a marked manner the secretion of saliva, but only when it is injected into the veins, this activity being immediately checked by atropin, differing in this latter respect from physostigmin.—*The Lancet.*

The Margaret Williamson Hospital.—In Shanghai, in the year 1885, was opened a hospital for the relief of Chinese women and children. It is under the control of the Woman's Union Missionary Society, of America, and originated in a fund left for that purpose by the late Mrs. Margaret Williamson. It is under the charge of Drs. Elizabeth Reifsnyder and Mary Gale, and Misses Elizabeth McKechnie and Elizabeth Andrews. The first report of the work, for the two years ending December 31, 1887, has just been issued. The greater part of the work is done in the dispensary, where as many as three hundred prescriptions have been filled in one day, and over three thousand patients treated in a single month. It is proposed soon to add to the capacity of the hospital by the erection of a new ward, which will bear the name of the late Dr. S. Wells Williams, the funds for the purpose having been bequeathed to the Mission by that well-known sinologue.

The Experiences of a Young Medical Witness.—"Once, when younger than now, it was my fate to figure in some such rôle in a divorce case, in which the wife sued her rich husband for a legal separation and alimony. One of her grievances was that he charged that, at marriage, she had gonorrhœa, with which she infected him. My evidence, given with the earnestness and zeal of one strong in the faith that she was a pure, slandered, wronged woman, was to the effect that, shortly before marriage, she was under my treatment for leucorrhœa, an ailment that even an expert might mistake for gonorrhœa; that a husband cohabiting with a wife thus afflicted might take on non-specific urethritis, and I gave it as my unqualified opinion that such were the conditions in the case pending. Well, she got her divorce, but the presiding judge refused to grant alimony, whether by reason of, or in spite of, my medical testimony that functionary never stated. Not long afterward, one who stood high as a nice moral young man called to see me, a picture of wretchedness and woe. He said there was something seriously wrong with his 'private parts,' he could not imagine what. Upon examination, an effort was made to relieve his mental anguish by the assurance that he could soon be relieved, as it was only a plain uncomplicated case of old-fashioned clap. This announcement was a shock and surprise. He said it could not be—it was impossible. In total disregard of these protestations, it was suggested that he had better tell where he got it, as such information might have an important bearing on treatment; whereupon, after a little hesitancy, he lifted up his voice and said: 'Well, Doc, I never fornicated with but one woman in my life, and never would have touched her had you not given her so excellent a character when a witness in her divorce case.' Thus the wretch made me a party to his woes, and, as soon as cured, skipped away into the unknown, after beating me out of my fee.

"Such is (professional) life in the far West." —Dr. H. J. Crumpton in *Medical Reporter.*

Like a Bird.—Dr. Wm. R. Lowman reports the case of a pregnant woman, two months advanced, who was frightened by a buzzard. Two weeks later she aborted. The fœtus was about three and one-half inches from tip of toe to end of neck. It was about the size of a robin and resembling that bird very much in contour—even to the skin, which was of that "fine goose-skin" variety, so characteristic of the winged family of animals. The umbilical cord was normally attached to the body and the placenta, which was somewhat larger than a half-dollar silver coin. The feet had the three main anterior digits, and the sudsidiary digit posterior with its long claw. The membranes were almost perfect. The freak was examined by Drs. W. C. Wannamaker, O. R. Lowman, and Dr. Lowman.

Saccharin in Cystitis.—In a paper read before the Royal Academy of Medicine in Ireland, Dr. James Little reported a case of chronic cystitis with ammoniacal urine occurring in a lady nearly eighty years of age. Decomposition of the urine was prevented by quinine and boric acid in fair doses, but the patient's stomach became so irritable that she could no longer take the remedy. Washing out the bladder was impossible, on account of the pain caused by the passage of the catheter. In this extremity Dr. Little bethought himself of saccharin tablets, and ordered the patient to take six daily. In three or four days the urine, which had been so offensive that the attendants were sickened by the odor, became purified, and although it still contained pus did not again become ammoniacal.—*Dublin Journal of Medical Science,* June, 1888.

Chicken Blood in Leucocythæmia.—Dr. Czartoryski reports, in the *Pacific Medical and Surgical Journal* for June, 1888, the case of a child suffering from the last stages of leucocythæmia. She was reduced to the last extremity, and seemed to be almost *in articulo mortis.* Fresh chicken blood was ordered, and as the father of the child was a cook in a restaurant, the treatment was easily carried out. On the first day the patient drank the blood of two chickens, and the amount was gradually increased until the blood of ten chickens was taken daily. The child immediately began to improve, and in seven months was apparently perfectly restored.

DISEASES OF THE EXTERNAL AUDITORY CANAL.

ABNORMALITIES—HYPERÆMIA—OTITIS EXTERNA CIRCUMSCRIPTA—OTITIS EXTERNA DIFFUSA—OTITIS EXTERNA DESQUAMATIVA—CERUMINAL ACCUMULATIONS—SEBORRHŒA—ASPERGILLUS.

By SAMUEL SEXTON, M.D.,

NEW YORK.

THE following remarks, being practical deductions from a considerable number of cases seen in the writer's practice, will, it is hoped, not be without interest for the general practitioner for whom they are more particularly intended.

ABNORMALITIES.—These include, under arrested development, absence of the external auditory canal, closure (atresia) by membranous or osseous tissues, abnormal width and congenital contraction. There may be also excessive development of this part of the ear, owing either to a thickening of the cutaneous lining or due to irregular development. A considerable number of persons have very large canals; the drum in such cases is much exposed to the free entrance of foreign bodies—water, draughts of air, and loud sounds. Where the meatus is large the Eustachian tube may also be of unusual size, thus favoring extension of disease per tuba by continuity of tissue, or by direct entrance of air or fluids through the tube. It is, at all events, very probable that the tympanum, in these cases of large canals and tubes, is very frequently more liable to attacks of disease from both directions. Among the many thousand cases of aural disease observed and recorded by the author were 411 with very large meatus, and concerning which notes were taken. Of these, 260 were males and 151 females. Among this number chronic catarrh of the middle ear occurred in 207 cases, acute catarrh in 24, and subacute catarrh in 18; while there were 77 cases of chronic purulent inflammation of the middle ear, and 47 of acute purulent inflammation. Collections of cerumen were found in 86 of this number, and otitis externa existed in 19 cases. A correspondingly large drum-head was usually present in these cases.

HYPERÆMIA.—Hyperæmia, or inflammation of the dermic layer of the inner end of the canal, is very common in processes of the same nature occurring in the middle ear. Dermatitis of the external auditory canal is of much more frequent occurrence than of the auricle. Irritation of the nerves in sympathetic relation with the ear—especially of the mouth and pharynx—is a cause of hyperæmia, and may even set up a genuine inflammation. Thus dentition, caries of the teeth, ulcers of the mouth or pharynx, enlarged tonsils, naso-pharyngeal disturbances, and polypoid growths in the nose, etc., conditions constantly met with, are causes of hyperæmia, which, when long continued, may lead to serious alterations in the nutrition of the parts affected. Results of this altered action of the part are increased secretion of the cerumen and exfoliations of the epidermis, two principal constituents in the accumulations found in the locality we are describing. To the latter subject reference will be made later on.

In looking over his cases of hyperæmia of the auditory canal, the writer finds that in almost every instance reflex irritation from the mouth (diseased teeth, etc.) existed. Many were associated with chronic catarrhal or acute purulent inflammation of the middle ear.

Strong mental action, and the use of alcoholic beverages, which play an important part in increasing cerebral circulation, often induce hyperæmia of the ears. Men are, of course, more subject to these conditions than women. Everyone has observed the flushing of the face and auricles under excitement. The aurist is familiar with the every-day statements of patients that they experience "burning in the ears;" and that the "ears itch," so that it is with difficulty they restrain from violently scratching the meatus with pins or anything convenient to use for the purpose. Hyperæmia, if moderate, may occasion only itching and dryness, with absence of ceruminous or other secretions.

OTITIS EXTERNA CIRCUMSCRIPTA.—Furunculous inflammation, which is described by Schwartze as a perifollicular inflammation in the skin, is especially liable to affect the outer extremity of the external auditory canal, and frequently, owing to the richness of this locality in connective tissue, the inflammation extends deeply and becomes phlegmonous in character. Furuncles just within the meatus may give rise to so little irritation as to be misleading and be taken for a tumor, as the integument in some cases is scarcely discolored. Furuncular inflammation may be the result of irritation from middle-ear discharge, coming on sometime during the course of middle-ear inflammation. It may also be consecutive to periostitis of the canal, and is very often induced by the employment of irritating drops, syringing, the rude handling of the speculum, probes, cotton-wool swabs, ear picks, etc. This inflammatory affection arises, furthermore, often in persons having a tendency to boils, acne, etc., and in cases where more or less reflex irritation from decayed teeth, and catarrhal conditions of the naso-pharynx exist; in women, especially during pregnancy, and when other uterine reflex irritations are present. The presence of accumulations of wax or of foreign bodies in the external auditory canal is conducive to an inflammation of these parts. Furuncles appear to be most abundant in the spring of the year, and during the hot weather, when persons are apt to be run down in health.

The *subjective symptoms* usually present are more or less intense pain, and deafness if the canal be occluded. Tinnitus aurium and vertigo occur also, owing to nervous irritation and disturbance of the tension of the drum-membrane. The parts about the auricle are apt to be tender to the touch, especially in the neighborhood of the tragus, and traction on the auricle itself is generally painful.

Of 197 recorded cases, 93 were males and 104 females. Among the males there were but ten cases under ten years of age, the youngest being respectively seven and nine months old. Only seven of the female patients were under ten years of age, the two youngest respectively seven and eight months. The fact that in 109 of these patients there existed decided reflex irritation from decayed teeth, cutting of wisdom-teeth, etc., is instructive from what has been said before on this subject. Catarrh of the upper air-passages, hypertrophied tonsils, etc., existed in 61 cases, and 38 patients had chronic catarrh of the middle ear. In 2 cases, the furunculous inflammation was consecutive to acute catarrhal otitis media; in 12 cases, to acute purulent otitis mdeia, while in 22 cases it was, to all appearances, caused by irritation from the discharge in coexisting chronic purulent inflammation of the middle ear.

The disease appears to have been caused in 8 cases by sea-bathing, and in a number by trauma of various kinds, such as the scratching of the canal with pins, a blow on the ear, etc. Among the women were 22 where decided reflex irritation from uterine disturbances existed, due to pregnancy, childbirth, etc. In the large majority of these cases, pain, more or less severe, was present, and tinnitus aurium. Vertigo existed in 7 cases, and autophonous symptoms in 12. The disease was recurrent in 6 patients.

In examining patients with circumscribed inflammation of the canal, care should be exercised in introducing the speculum, as the procedure invariably causes much pain. Sometimes the swelling of the walls of the canal is so great that complete occlusion of the deeper parts is present. The meatus is often filled with *débris*, and, when seen, the drum-head and inner end of the canal have a macerated appearance.

In many cases it will be found extremely difficult to differentiate between circumscribed and the diffuse forms of inflammation of the auditory canal, as the symptoms are very similar, and the former has often a tendency to run into the latter. The swelling in the canal is, however, more localized in furuncular inflammation, as is also the tenderness; conditions which can be tested by touching with a probe. Differential diagnosis between circumscribed and diffuse inflammation of the external auditory canal and purulent inflammation of the middle ear is not always easy, for in the diffuse form of inflammation there is frequently active hyperæmia of the middle ear, and the discharge from furuncles may simulate an otitis media purulenta, though it is usually scant and very thick. Where multiple furuncles exist the canal is liable to be completely occluded. The favorite seat of furuncles is on the anterior inferior wall, just within the meatus, the swelling giving the lumen a triangular appearance.

Treatment.—Incisions into the canal should not be made at random, for often the precise spot of inflammation, comprising a distended follicle, can be discovered on careful search, and an incision into this point will usually be followed by speedy relief. Incisions of furuncles are, however, in some cases, liable to close up in a few hours, the pressure of the canal walls favoring this where the furuncles fill the canal. The openings should be made pretty large in order to give free exit to the thick tenacious matter. In some nervous subjects the operation is illy borne, and is at times unadvisable; in children the administration of a limited quantity of ether or chloroform is advisable.

Many still adhere to the treatment with leeches in these cases. Some patients are, however, made much worse by this procedure, and from the author's own experience better success generally attends other treatment. It is in these cases that sulphur and its compounds seem to act with especial advantage. That sulphur has long possessed great repute as a curative agent, both in the profession and among the laity, is a fact well known. The appearance of furuncles should not, the author believes, be regarded altogether as a local trouble, but generally as a manifestation of systemic disturbance. Sulphur seems to act as a corrective in the function of digestion, and especially so in run-down persons, and as such undoubtedly assists very materially in improving the general health of these patients. In the aggressive stage calcium sulphide, given in doses of one-tenth to one-twentieth of a grain, every two hours, or soon after food has been taken, has been generally found to be beneficial. Pain may be relieved with the tincture of aconite in small and frequently repeated doses; and warm applications and fomentations may also be applied in some cases, but their excessive use should be avoided. An ointment composed of equal parts of ung. belladonnæ and vaseline is a valuable remedy in painful affections of the canal. It may be smeared over the parts two or three times a day, or a pellet of absorbent cotton-wool may be used as a vehicle and left in the canal when its presence is borne.

Otitis Externa Diffusa.—Diffuse inflammation in the skin of the meatus, although liable to result in abscesses, etc., at the outer third of the canal, is most frequently found in the deeper portions, where, owing to the absence of connective tissue, its behavior is different, and there is likely to be periostitis as well as an extension of the inflammation to the drum-head.

The disease appears in the acute and chronic form.

Acute diffuse inflammation of the meatus does not often occur without involving the membrana tympani; neither does acute inflammation of the tympanum often occur without more or less affecting the inner end of the external auditory canal. It may be caused by chronic eczema of the auricle, or follow the removal of polypi, and, as not infrequently happens, it may be produced by rude handling of instruments, etc. In some instances it seems to be due to exposure to cold draughts of air, and it is very frequently the result of getting cold water in the ear while bathing in the sea, cold salt water being particularly irritating. Among 191 cases of diffuse otitis externa, there were 105 of the acute form of the disease. In 40 of the latter number the cause of the affection could be traced to sea-bathing, and in 5 to the effect of Russian or Turkish baths. Many of these acute cases were due to traumatism of various kinds, such as attempts at removing foreign bodies, cerumen-plugs, etc., from the canal. The disease is frequently due to reflex nervous influences arising from oral irritation, catarrh of the naso-pharynx, etc., and more remote disorders of the system, as described with furunculosis. Of 191 cases, 124 were males, 67 females. The greater frequency of the affection among males is undoubtedly owing, in some degree at least, to their greater exposure to vicissitudes of climate and weather, out-door life, occupations, etc. Twenty-three of the cases were associated with acute purulent otitis media, 17 with chronic purulent otitis media, and 8 with acute catarrh of the middle ear. In the large majority of these patients there was more or less irritation from carious teeth, and the greater number of them were subject to head colds, etc.

Subjective symptoms.—There is generally a sensation of burning, at first, in the ear, and in the milder cases more or less itching. Pain, of course, is present in greater or less degree, as well as tinnitus aurium, deafness, and, in many cases, autophonous and vertiginous phenomena.

Objective symptoms.—When examined, the integument of the canal will generally be found red and inflamed, or much swollen and very tender to the touch. The drum-head, when seen, often has a macerated appearance, or is deeply injected. The objective symptoms frequently resemble very closely those of circumscribed otitis externa. In some cases the inflammation may involve the connective tissue and extend out over the mastoid and parts about the ear. Abscesses are not infrequently the outcome of this, and periostitis is not an uncommon occurrence. In the older cases, where the disease assumes a chronic character, itching, and some loss in the hearing power, will generally be found. The integument becomes thickened and desquamating, the canal being often found partially filled with scales of epidermis.

Treatment.—Incision of the external canal will, in some few cases, be found necessary to relieve tension or purulent collections; and calcium sulphide and aconite are generally indicated.

General care, including hygienic measures and rest, must be urged in the more severe cases.

Otitis Externa Desquamativa s. Exfoliativa.—Desquamative inflammation of the external auditory canal occurs as an acute and also as a chronic process. It is, however, mostly found in the acute form. It is generally in run-down, intemperate persons and unhealthy children that we see the disease. Numerous reflex causes in remote parts of the body, such as have been already described in connection with the circumscribed and diffuse forms of inflammation of the external auditory canal, frequently give rise to the trouble.

There is but little if any discharge from the parts of anything excepting the pasty desquamative matter, or an entire exfoliation of necrotic epidermis. In some cases the whole of the dermic lining of the canal, including that of the membrana tympani, will be detached, resembling when removed the form of a glove-finger.

The affection is usually painless throughout, and this fact will aid materially in the establishment of a differential diagnosis between this disease and chronic diffuse inflammation of the parts. Pruritus and tinnitus aurium, caused by the presence of the accumulated epidermis-scales, are prominent symptoms of this trouble.

Treatment.—Relief may be attained by removing the scales, etc., by moderate syringing, and by insufflating powdered boracic or salicylic acid. When the desquamation diminishes, the use of the syringe should be discontinued in the treatment. The canal, of course, should be thoroughly, but very gently, dried out, after syringing, with cotton-wool before the powder is applied.

CERUMINAL ACCUMULATIONS.—These are of frequent occurrence, and when impacted, or efforts at their removal are unavailing, may give rise to much distress. Accumulations of wax are generally inspissated in consequence of the evaporation of their fluid constituents; but sometimes the mass remains soft for a long period of time, impaction in such cases seeming to occur from the continued deposition of cerumen upon that portion of the collection presenting inwardly.

Cerumen is sometimes secreted very rapidly, often flowing freely out of the canal in a semi-fluid state, when it is liable to be mistaken for purulent matter. The writer has had a number of children brought to him where the presence of such a secretion has been the cause of much anxiety to parents.

In health the moderate secretions of the external auditory canal disappear usually by evaporation and desquamation, the exfoliated matter falling out as quickly as formed.

The smaller collections of wax are found adherent to the epidermis, especially where the small hairs of the part are abundant. These collections frequently fall out, little by little, of themselves, or are removed by picking the ear. In some instances, however, the escape of even the natural secretions is prevented by collapse of the cartilaginous walls of the canal; and in some of these cases the imprisoned matter receives daily contributions from without, owing to the efforts of the patient at cleansing the concha during ablutions, the act working particles of dust, soap, etc., past the valve-like closure of the lumen.

The location of accumulations depends somewhat on the number and position of the ceruminous glands, the number of hairs, the size and curvature of the canal, and the movements of the jaws in mastication. The latter would seem, in some cases, to press the wax first against the posterior wall, and afterward, as the quantity increases, impel it backward toward the upper edge of the drum-head; the latter movement, however, would be influenced by the size and curvature of the canal. The writer's observations would seem to show that the location of cerumen may depend on the source of the exciting cause. Thus an enlarged tonsil may cause the wax to accumulate on the posterior walls of the meatus, as observed in one case in particular, where the condition of the teeth was excellent.

Collections of wax, whether soft or hard, frequently exert pressure of greater or less extent on the drum-membrane, especially at its upper segment, which part projects more than any other portion. This may keep up a constant state of hyperæmia of the membrane, leading finally to trophic changes, or even to inflammation.

Etiology.—It appears from the following table, showing ages and sex of 800 cases of ceruminal accumulations, that the trouble is found in individuals of all ages, and in males much more frequently than in females:

Table showing Sex and Age in 800 Cases of Cerumen.

Age.	Males.	Females.
4 months	2	
Between 1 and 2 years	1	1
“ 2 “ 3 “	5	2
“ 3 “ 4 “	2	1
“ 4 “ 5 “	5	6
“ 5 “ 15 “	42	51
“ 15 “ 25 “	84	42
“ 25 “ 45 “	229	86
Over 45 years	175	66
	545	255
Total		800.

We find, in reviewing this table, that the male subjects more than double those of the opposite sex, and that this affection is quite common in childhood. Indeed, a large number of persons, at some period or other of their lives, have experienced greater or less inconvenience from this cause.

Accumulations are mostly bilateral, and therefore in every instance both ears should be examined. It happens, however, as will be seen below, that one ear alone may be the seat of such a collection. Among the author's cases the accumulations were found in 397 cases in both ears; 146 cases in the right ear; 180 cases in the left ear. In the 77 remaining cases the affected ear was not recorded. It has long been known to otologists that accumulations in the external auditory canal are frequently associated with other abnormal conditions of the ear. The author is convinced, however, that more thorough observations will prove, in the majority of cases, that such collections are almost in variably due to diseased action elsewhere.

Causes.—One of the most important of the numerous causative influences in exciting the accumulations of cerumen is hyperæmia of the canal. Dentition, diseased teeth, ulcerated and inflamed conditions of the gums and mouth generally, also catarrhal conditions of the pharynx, etc., are all conducive to an excessive secretion of wax, owing to the hyperæmia excited by means of the sympathetic relationship of these parts to the ear. Thus we find that among these 800 cases of ceruminal accumulations, 601 of the patients were suffering from marked catarrh of the upper air-tract, enlarged tonsils, and, furthermore, from dental irritation caused by decayed and dead teeth.

Inflammations of the middle ear seldom fail to induce hyperæmia or even inflammation of that portion of the external meatus immediately connected with it by continuity, and the inflammatory affections of the meatus itself have even a greater tendency than the foregoing to produce accumulations which obstruct the canal to a greater or less degree. In one hundred and sixty-five ears from which Toynbee removed accumulations, only sixty were free from other aural disease. In the 800 cases of the writer were found:

238 cases associated with chronic catarrhal otitis media.
9 “ “ “ acute “ “
52 “ “ “ chronic purulent “
26 “ “ “ acute “ “

The free growth of hair in the meatus, found most frequently in those beyond middle life, and mostly in men, furnishes a nidus for accumulations, as it prevents the escape of flakes of cast-off epidermis and cerumen.

Operatives in dusty employments are subject to accumulations in which dust is found to be an important part. Foreign bodies furnish the nucleus for accumulations in many instances. Their presence is an excitant to the secretory function of the integument of the meatus, and they also prevent the escape of the flakes of dried cerumen as they form. The imprisoned object may consist of a pledget of wool or other substance, introduced to convey a medicament, or to protect the ear from the atmosphere, and carelessly allowed to remain until its presence is forgotten.

Among the cases mentioned were eight where the centre of the accumulation was formed by a foreign body.

It is not an infrequent amusement of childhood to put into the meatus cherry-pits, grains of corn, peas, beads, and the like, which may remain for years quietly embedded in the accumulations which their presence attracts. Vermin may become lodged in the meatus and, being unable to escape, remain to be surrounded by accumulations of cerumen. The bodies of various insects have thus been often found.

The exanthemata, as is well known, are often followed by aural disease; the hyperæmia and inflammation from this source are of course the same as from the causes previously mentioned. Large accumulations arising from this cause in young children have come under the observation of the writer. Thus, accumulations were found in 6 cases following scarlet fever, in 4 after measles, in 3 after diphtheria, and in 2 after typhoid fever.

Inspissated pus and other products of chronic purulent inflammation of the middle ear may contribute to these formations, but when the discharge is abundant it keeps the canal free. Such are the more frequent causes of accumulations in the external auditory canal. When the drum-head is absent the tympanic cavity is also likely to be occupied by the collection.

Character of the accumulations.—The appearance of accumulations will vary according to their character and the stage of the process. After inflammations of the middle ear the inner extremity of the meatus will always be found to have been involved, as the integument in that locality is far more delicate than in any other portion of the canal. We have to deal here with non-suppurative inflammations more especially, and in them we shall find the epidermis loosened and more or less humid where it joins the drum-head. Frequently there will be found an admixture of cerumen in these exfoliations.

Soft cerumen in small quantities is formed now and then upon the walls of the meatus of most people, and if undisturbed it may undergo gradual desiccation and fall out of the meatus unobserved. Where it has been secreted in slight excess, and where the meatus was large enough to receive the finger or some object used to wipe it out, the author has observed the cerumen spread over the walls by the wiping process until it adhered as a hard coating, which could not be removed without bringing away portions of the underlying epidermis. This soft cerumen, however, frequently collects in the meatus in such quantity as to completely fill it from the drum-head or near it to within ten or fifteen millimetres of the outlet. Its consistence will allow the passage through it of a probe or curette. Inspissated cerumen is the term usually applied to this mass. Hard, desiccated masses are formed by the complete evaporation of the aqueous constituent of the collection. They are usually of a dark-brown color, and often appear polished when seen from without. But whatever the nature of the accumulation, it will be found to contain more or less epidermis; sometimes, indeed, layer after layer of exfoliations will be found in a mass which, after removal, has been allowed to macerate in water.

Of course, from what has been said in describing the origin of accumulations, we may expect occasionally to find them containing hairs, pus, foreign bodies, etc. It is after adult life that most of the prominent collections are met with, the hard, desiccated variety being observed mostly in the aged, where the drying goes slowly on until the plug has an almost metallic density.

Symptoms of the presence of accumulations.—Itching forms one of the first and most distressing symptoms, giving rise to great general discomfort. Tinnitus is furthermore a very general symptom, causing much annoyance to the patient, as does also "ear cough" as it is called. When a collection of soft cerumen is present, the patient often complains of a "stuffy" feeling in the ears and of "muffled" hearing. Movements of wax or of other collections in the meatus sometimes awaken the patient at night. Among the writer's cases are 10 patients who suffered much from otalgia, 29 from facial neuralgia, and 264 with distressing autophonia, tinnitus aurium, and vertigo. Great deafness is not usually present, although the accumulations may almost completely close the canal. It was a marked symptom in but 15 of the cases. The writer has observed cases of this kind where there seemed to be better hearing for certain sounds than usual. One case is worthy of mention here: A brakeman employed upon a railway freight-train had both ears seemingly completely closed by hard accumulations. Examination by voice and watch resulted in demonstrating better hearing than usual. He maintained that he could hear the engine's signals, when he was at the rear of a long train of cars, better than any other person in the same position. The removal of the accumulations was not followed by any improvement in hearing.

The collections touch the drum-head in these cases occasionally; we have the statement of Toynbee that the collection, when removed, sometimes has a cast of the membrane upon it. It is certain, however, that when impaction takes place, the normal vibrations of the membrane are interfered with, and that tinnitus and deafness occur.

Impaction of accumulations.—Ceruminal collections of all sizes and conditions may remain for years without observable deafness or other symptoms of their presence. Sooner or later, however, they are liable to become suddenly displaced. This accident usually results from water entering the meatus while the patient is bathing—notably in the Russian bath—or from the introduction of a finger or the roll of the napkin in the subsequent endeavor to cleanse and dry the canal. Or the accumulation may be loosened by sweating, going into a moist atmosphere, by a blow upon the ear, or any violent jarring of the body. An unpleasant sensation in the ear has induced patients to seek relief by pouring some medicament into the meatus, such as olive-oil, spirits of camphor, chloroform, laudanum, gin, and other liquors, and when an accumulation has been present these efforts at relief have caused impaction to take place. Impaction is seldom observed in children, and they do not often complain of tinnitus. Accumulations are therefore not apt to be observed unless the patient is examined for some inflammatory condition attended with earache or deafness. The latter symptom — deafness — is usually disregarded both by parents and teachers until it becomes very marked. It should be an invariable rule to examine the ears of children who have recently had scarlet fever, measles, diphtheria, whooping-cough, or severe colds, since accumulations may occur in the canal, and give rise to much irritation without the real cause being suspected.

In the 100 cases of impacted cerumen recorded, among the causes were: Sea- or surf-bathing in 27 cases, Russian baths in two cases, washing head or ears in four, maltreatment in one, a violent fall in three cases, a blow of the hand on the auricle in two, concussion of thunder in one, the compression of air in a railroad tunnel in one, and in one the highly condensed air in a submarine caisson. In a large number of instances no special cause could be discovered, but many of them were doubtless due to loosening of the plug from sweating, or its detachment from the walls of the canal in consequence of shrinkage; when slight movements of the head or lying upon the opposite ear were attended by displacement.

The plug, when loosened, sooner or later impinges upon the drum-head, the pressure being followed by noises in the ear, often very distressing; sometimes by pain and vertigo. Sometimes the patient is almost distracted by these symptoms, especially when they are associated with autophonia and deafness. Motions of the head, or traction upon the auricle, are sufficient to temporarily release the plug in most instances from time to time; the intervals of immunity lasting from a few hours to days or weeks, according to circumstances. If the pressure is caused by a dry, and consequently hard plug, the drum-head may be much injured by its presence, and hyperæmia or inflammation follow. The sudden displacement and consequent impaction is frequently accompanied by a loud report in the ear, resembling the discharge of a pistol or other explosive sound.

Sometimes, as has been stated, accumulations form gradally *upon* the drum-head; the sudden separation of these would be likely to give rise to objective sounds such as occur from sudden impaction. The presence of a hard, loose plug of wax interfering with the movements of the temporo-maxillary articulation sometimes gives rise to inflammation of the external auditory canal, when the movements of the lower jaw are much limited from the pain experienced in the glenoid fossa. This state of things sometimes offers the first intimation we have of the existence of these accumulations.

Inflammation of the middle ear arising during the presence of plugs may also bring them to notice.

Treatment.—The removal of cerumen usually is not difficult; it should never be undertaken, however, especially by the inexpert, without due preparation, since a failure usually leaves the patient worse than before; for inefficient syringing may serve to only further increase the impaction. Difficulties are liable to arise in some cases owing to the tortuous nature of the canal; in others to the character of the plug, which may be of so tenacious a consistence, and so tightly wedged in the canal, that syringing alone will not bring it away.

Ceruminal collections, when impacted, should be removed without delay. In the greater number of cases the syringe is the best instrument for this purpose. Much disappointment may be avoided by using a suitable syringe for this work. The best one the writer has yet found was made for him by Mr. Ford; the barrel is of glass, the mounting of hard rubber. Where syringing fails dressing forceps and the foreign-body curette may be cautiously employed to loosen the mass, when it in most cases will be easily removed by syringing.

The operator in no instance should proceed until the ear has been carefully examined under a good light; the best illumination being afforded by the electric head lantern, though a forehead mirror usually is sufficient. In syringing, the operator will find it best to seize the auricle with the left hand and pull it upward, backward, and outward, exposing more freely in this manner the opening of the meatus. The syringe, filled with water as warm as can be conveniently borne by the patient, is held in the right hand. The water and *débris* escaping from the ear during the syringing are caught in a cup or basin held beneath the ear by the patient himself, or by an assistant. If the accumulation is very hard, and completely fills the meatus, the stream of water should be directed with decided force against one edge of the plug, preferably the upper side. Usually a few syringefuls are sufficient to dislodge the mass and somewhat soften it—sometimes bringing it away. If it remains in the canal it can be seized with aural dressing-forceps and removed. Should a continuance of the syringing be determined necessary, frequent inspection should be made with a speculum as the operation proceeds.

The soft or scaly collections require more gentle syringing.

After any syringing there will usually be seen lying upon the meatus-walls small particles of loosened epidermis. They must be cautiously picked out with forceps under illumination, using care not to forcibly detach any of them; though with the best of care there will at times be left denudations.

Sometimes these denudations are extensive, leaving bleeding patches upon the walls of the meatus. We may have in such cases subsequent diffuse or furuncular inflammation.

The membrane, after the operation of syringing, has a macerated and injected appearance, which, however, rapidly disappears.

After we are through syringing, the meatus is to be dried by gently passing in a small portion of absorbent cotton-wool wound upon the end of a vulcanite carrier or held in the grasp of the dressing-forceps. A pledget of wool should be left in the meatus if the patient exposes himself to the open air after the operation.

Coughing and dizziness are phenomena of common occurrence while syringing proceeds, but they quickly pass away, and are not alarming symptoms.

A return of accumulations is of frequent occurrence, depending, of course, upon the cause.

A considerable accumulation of soft cerumen often takes place in a few weeks, and in twelve or eighteen months, unless causative action ceases, a considerable plug may confidently be anticipated in many individuals.

If the remote causes of the collections are sought, and treatment be directed to them, we may hope in many instances to prevent their return.

Keratosis obturans.—A tough, pasty mass, first described by Wreden;[1] is found sometimes, but rarely, in the external auditory canal, and is exceedingly difficult of removal. It apparently consists of modified sebaceous matter, having the tenacity of fibrous tissue. It usually remains adherent to the inner portion of the canal and to more or less of the drum-head's surface. The writer has met with but few cases in a long experience. Burnett[2] states that but few cases have come under his observation. From the closely adherent condition of the collection under discussion, the writer has been inclined to believe that it was composed of matter which is a product of inflammatory action. It is of rather light color, and does not seem to become inspissated like the endogenous collections, which easily dissolve in water, and on unfolding themselves develop layers of exfoliated epithelium and sebaceous matter.

The removal of this substance is extremely difficult; it must be detached little by little, using the syringe occasionally for the removal of detritus. The biting forceps and foreign-body curette are of service, as well as the ordinary dressing-forceps. The patient can scarcely endure efforts at removal for more than half an hour, and it is probably the best plan to resort to several sittings. Even with the utmost care, some denudation of the canal-walls or drum-head is likely to occur. No one unaccustomed to the employment of aural instruments would be warranted in operating upon these cases.

SEBORRHŒA.—This disease, characterized by an increased exudation or hypersecretion of sebum, which then dries on the surface of the skin, forming small scales and flakes, is sometimes found occurring in the auditory canal. In most cases both ears will be affected. According to most authors, females are more frequently troubled with this affection than males. Among 51 cases recorded by the writer and occurring in his practice, however, 27 were males and 24 females.

The disease is generally recurrent and occurs mostly among neuropathic, run-down, and intemperate individuals, and also among those subjected to continual worry and mental strain.

Symptoms.—Itching, noises in the ear, and more or less loss of the hearing power, are the usual subjective symptoms observed. The canal is found more or less filled with a mass of whitish, or whitish-brown scales, on the removal of which the skin of the meatus will be seen to be red and more or less tender to the touch. Eczema, which seborrhœa of the canal may resemble in some few instances, is very seldom found confined to the meatus alone, but spreads, in the larger number of cases from the auricle to the canal.

Treatment.—The masses of dried sebum should be removed by syringing and the exposed surface well but gently dried; boracic acid in powder may be insufflated if secretion continues. When the patient is run-down and otherwise in poor health, attention to the general condition should of course be given, and rest, etc., recommended.

Aspergillus.—The presence of a fungus in the external auditory canal during the existence of other pathological conditions is sometimes so marked a feature as to attract especial attention. Several varieties of this vegetable parasite are known to occur; they give the particular color to the mould—thus *Aspergillus glaucus* presents a somewhat grayish aspect, while *Aspergillus nigricans* is dark.

The deep part of the external auditory canal in the neighborhood of the drum-head, where the parts are more humid, is that most frequently attacked by this fungus, and in a very considerable number of cases the membrana tympani is itself attacked. Aspergillus has been observed by some writers to grow in the cavity of the middle ear. Mould is also often found on the walls of the meatus, usually springing from a light deposit of cerumen which is spread over the canal.

Aspergillus will be generally observed appearing in the course of chronic purulent diseases of the middle ear, or where there is an increased secretion of the canal. In the author's own experience, mould is most commonly met with in seborrhœa and desquamative dermatitis of the canal, owing to the humidity usually present in these affections; sometimes a dermic sac which has been thrown off from the canal and drum-head and removed entire has been thus found to be lined with a delicate layer of aspergillus. It is also found when moderate otorrhœa exists and the canal is coated with a layer of inspissated pus. The writer has not observed in any of his cases that the presence of this vegetable growth complicated to any great extent the diseases which it accompanied, but some writers allege that much irritation may be caused by its presence. Among these authorities should be included Dr. Charles H. Burnett, whose contributions to this subject will be found of much interest.[1] The reader would also do well to consult his work for a more complete and exhaustive essay on this subject.[2]

As regards the *subjective symptoms* accompanying the presence of aspergillus in the ear, it may be stated that these are usually noises in the ear, pain more or less severe, and occasionally vertigo. Itching, a sensation of burning, and even in some cases more or less interference with hearing are other symptoms frequently observed.

Treatment.—Instillations of alcohol, carbolic acid, and various other antiseptic fluids are used for the purpose of destroying the fungus, and also, it should be added, insufflations of boracic acid and other powders. Cleanliness, by means of syringing, and dryness, is the only treatment, however, the writer has found it necessary to employ, besides attention to other morbid conditions upon which the existence of these fungi seemingly depends.

Hernia of the Testicle.—M. Kirmission spoke recently on hernia of the testicle at the Paris Société de Chirurgie. A man after a severe contusion of the scrotum presented a hernia of both organs. The right remained covered with its vaginal tunic, but the left was found to be impossible to retain in position by ordinary means. A pin was finally passed through the gland, and the result was very satisfactory. M. Tillaux said that he did not see why the operator did not enlarge the wound and thus allow the testicle to return without having to employ a pin. M. Anger thought that there must have been a rather considerable loss of substance. In a similar case he was obliged to ablate the organ. M. Kirmission considered that nothing in such cases could justify castration, for he had known two cases in which, it not being found possible to reduce the organs, they were left exposed; at the end of two days the surfaces granulated, and soon the testicles were completely covered. — *The Medical Press.*

SOME CLINICAL FEATURES OF DIPHTHERIA AND THE TREATMENT BY PEROXIDE OF HYDROGEN.

By GEORGE B. HOPE, M.D.,

SURGEON METROPOLITAN THROAT HOSPITAL; PROFESSOR DISEASES OF THROAT, UNIVERSITY OF VERMONT.

The sentiment, so long divided, with regard to the constitutional or local inception of diphtheria, seems to be now almost universal in the direction of the latter theory. Consequently, in the light of this opinion, it is clear that the rational treatment must rest more on the recognition of some local agent which will surely destroy the specific germ before a full development of the constitutional infection is reached, rather than on any system of general medication which might be presumed to act more or less as an antidote in combating the septic influences occurring in the course of the disease.

The favor with which intubation is received appears to point in a measure to a realization of the fact that all present remedies, local or constitutional, serve but a very insecure reliance toward controlling the invasion and extension of the so-called membraneous formation. Whatever benefit may be derived from the use of pigments in which iron, silver, zinc, iodine, alum, or certain of the mineral acids are the main principles, probably lies in their simple astringent or tonic action on the tissues, in closing the follicles and arresting the tendency to absorption rather than in any manner affecting the morbid elements themselves, unless, indeed, some of these agents are employed in sufficiently concentrated form to lead to the destruction of sound tissue as well, and thereby open fresh points for contagion.

On account of their poisonous or irritant nature the active germicides have a utility limited particularly to surface or open-wound applications, and their free use in reaching diphtheritic formations in the mouth or throat, particularly in children, is unfortunately not within the range of systematic treatment. In peroxide of hydrogen, however, it is confidently believed will be found, if not a specific, at least the most efficient topical agent in destroying the contagious element and limiting the spread of its formation, and at the same time a remedy which may be employed in the most thorough manner without dread of producing any vicious constitutional effect. Although the peroxide is by no means of recent date, its medicinal value has been chiefly confined to the cleansing of foul ulcers and suppurating wounds, and there is hardly more than a casual mention of its utility in the treatment of diphtheria previous to a paper of Dr. Mount Bleyer on this subject.[1] Quite independently of these observations, somewhat over eighteen months since, at the Metropolitan Throat Hospital, several cases of well-marked buccal diphtheria were treated with the peroxide, with the effect of confirming in the most satisfactory manner the results obtained by Dr. Bleyer. The report of these cases was consequently omitted, pending the experiences it was supposed others would be quick to furnish on a more extended scale of the new remedy so warmly advocated. Among the somewhat small number of trial cases which have appeared at various times in the medical press, there are none in which a distinctly negative opinion is expressed, and where only a partially satisfactory result is attained there has appeared to be sufficient cause to permit a reasonable explanation for the fact.

In common with all forms of treatment promising particular or specific results, there are apt to be two substantial reasons which would naturally lead to disappointment. The first lies in the fact that improper cases are selected for experiment. In this category are included those where the disease has already passed the boundary of simple pathological conditions, either on account of a special severity of the attack in its incipiency, or, what is identical, a vitiated constitution, where secondary symptoms occur at a much earlier stage and tending to a necessarily fatal termination. It has been frequently stated in other connections that the practice of medicine is to be regarded as an art, not a science in the true sense of the term ; that an exact result may not be predicated in any physical derangement, no matter how far the intrinsic effect of drug or treatment may have been determined. The study of the microscopic germ organism as the cause of disease leaves unanswered the vital principle in its clinical aspects as to relations of intensity and effect. Hence in diphtheria, where, pre-eminently, secondary conditions are to be expected, a delay in appreciating the early manifestations of the attack will place the resisting power at a minimum, and any particular value in a given line of treatment is to be measured by just such a ratio in anticipating its results.

[1] The Medical Record, August 13, 1887.

The question is frequently raised as to the identity of follicular tonsillitis and specific diphtheria. While, in the experience of the writer, no case of follicular tonsillitis, however pronounced, has been seen to pass into the local or constitutional phases of diphtheria, and, moreover, similar attacks occurring in the same individual at successive periods, without complications, clearly point to a like conclusion, it is equally true that diphtheria is commonly, if not generally, marked by an early follicular manifestation that may not be readily distinguished from a simple inflammatory process involving merely the tonsillar crypts. However paradoxical these views may seem at first sight, the illustration of their bearing is found in the sharp boundary-line which determines the favorable career of follicular tonsillitis, on the part of those whose experience lies particularly within the range of throat diseases, as compared with the uncertain diagnosis of diphtheria so common in the reports of cases in the hands of the general practitioner. It is with no intention of hypercriticism that this statement is made, which the experience of many can attest, but merely to emphasize the fact that too little discrimination is exercised in the recognition of two diseases altogether dissimilar in their nature and in their demands for appropriate treatment. In this connection it may not be amiss to quote, from a recent paper entitled "The Therapeutics of Diphtheria," [1] the following statements: "Diphtheria is a contagious disease. Severe forms may beget mild or severe cases. There is probably no spontaneous origin of diphtheria any more than there is a spontaneous origin of cholera or scarlatina. What has been called follicular amygdalitis (or tonsillitis) is diphtheria in many, perhaps most, instances. It is seldom dangerous to the patient, because the tonsils have but little lymph communication with the rest of the body. But the diphtheritic variety of follicular amygdalitis also is contagious."

Within the foregoing statements, quoted in their context, are two propositions which are certainly diametrically opposed, unless, indeed, the intention of the author was to reconcile them by a middle ground, which, to say the least, contains the most ambiguous meaning, by the use of the term "diphtheritic variety of follicular amygdalitis." Furthermore, any reasonable explanation is disturbed by a paragraph following (p. 8): "Indeed, many cases of throat disease occurring during the prevalence of an epidemic of diphtheria are but those of pharyngitis, which, under favorable circumstances, may develop into diphtheria." Are we to understand that diphtheria—a specific spontaneous disease—is identical with follicular amygdalitis with its simple prognosis ; in other words, an intrinsically abortive diphtheria, and may we not question that pathology which would have us believe that under favorable circumstances a pharyngitis or tonsillitis may "develop" into diphtheria ? Unquestionably inflammatory conditions, acute and chronic, or lesions of continuity of these parts will predispose to the reception of the contagious conditions of diphtheria, but it should be distinctly understood that the disease, whether mild or severe, must, in its *origin*, start as a true diphtheritic formation.

A further explanation for the uncertain results attending the use of the peroxide lies in the direction of the preparation itself, as also in the manner of its topical application. The usual descriptions allow the diluted strength of from three to seven volumes of distilled water. Inasmuch as the efficacy depends upon the ozonized oxygen in solution it has seemed desirable to rely on the full strength of the officinal preparation of fifteen volumes, especially when used in the fauces, where any slight irritation from its acidity is not apparent. In all the cases treated, a fresh, standard Marchand preparation of fifteen volumes was that on which the experience of the writer has been based. An equally important element is in making the application in such a manner as to produce the most determined effect on the diseased tissues, with as little local disturbance as possible. Swabbing the tonsils and pharynx is the rough and ready method commonly resorted to, with the second motive of detaching, if possible, the membraneous formation. Such treatment is not only unnecessarily harsh toward the patient, but also in intrinsic efficacy falls far short in securing the best therapeutic value of the remedy. It is properly recognized that the removal of the membrane, unless it occurs spontaneously, is not favorable to the local conditions ; moreover, the glairy mucus coating the surfaces does not permit the application to come fairly in contact with the disease, or so superficially as to require the most constant repetition. The latter criticism holds the same bearing, only modified in a degree, to the hand-ball vapor and spray-producing instruments that have been recommended.

A steady coarse spray, with an air-pressure of twenty pounds or more, will, in a few moments' time, produce a more positive action than prolonged efforts to reach the fauces by means of cotton applicators. The force of the spray should be sufficient to cleanse at once the surface accumulations, as it destroys the necrosial elements with which it comes in contact. In this manner the removal of the *débris* and the action on the deeper structures go hand in hand.

It will be noticed that immediately on contact with the peroxide a white, cloudy coagulum is formed on and about the diphtheritic patches, readily floated off and exposing a more sharply defined and a flatter, smooth, and whiter base. Properly speaking, there is no liquefaction of the exudation, but the decomposition of the inflammatory products is so complete that the cells are broken up and freed from the entangling fibrous net-work beneath. In a particular instance in the case of apparently a continuous diphtheritic slough, involving the tonsils and extending in an unbroken line across the margin of the soft palate, a solitary application exhibited this effect to such a degree that the natural color of the mucous membrane appeared in spots as if the exudation might have bridged across sound tissue without as yet securing attachment to the subepithelial layers.

How frequently the treatment is to be followed up depends to a considerable extent on the density as well as the area of the surface involved. It may be said, however, that two applications a day, in the great majority of cases, should be sufficient, if thoroughly performed, to arrest all danger of extension and accomplish the gradual resolution of the local formation.

If the experience of the writer is confirmed, it is apparent how much time, trouble, and unnecessary handling is obviated when contrasted with the methods outlining hourly or half-hourly swabbing, or, as one has more frankly expressed it, "scrubbing," with nauseating applications and culminating in the exhaustion of the patient, if not the most indifferent success. No reasonable objection can be raised either on the score of the expense or the difficulty of transporting the apparatus necessary, as small portable air-receivers can be readily obtained in the instrument shops, on the model of those devised by Codman & Shurtleff, of Boston, and which for the purpose are equally efficient as the larger stationary office fixtures.

---

[1] A. Jacobi, reprint.

The more recent experience of Dr. Gifford,[1] establishing the active germicidal properties of peroxide of hydrogen, rapidly diminishing in proportion to its dilution in what might be called a geometrical ratio, appears to emphasize in a marked degree the clinical observations on which the main features relating to its employment have been based.

PAPOID AND VERATRUM VIRIDE IN DIPHTHERIA.

By J. D. BRUCE, M.D.,
PROSPERITY, S. C.

THE quest after a "remedy for diphtheria" finds no readier sympathy from me than I should give to a search after a remedy for fevers—for identically the same reasons; and which are apparent without further statement. Nor am I disposed to try any one remedy which is claimed to possess such potency; yet I am ever ready to give trial to any remedy which addresses itself to my mind as possessing qualities that would clearly meet any one or more indications, in the treatment of that truly terrible disease. As soon as I was informed that papoid had the unusual property of a solvent, acting alike in the presence of an alkali or an acid, I determined to give it a trial in diphtheria. But it has only been within the last few weeks that I have had the opportunity of putting it to the test in clearly typical cases.

On August 10th I was summoned to see a child, aged thirteen months. He was a stout, well-grown child, with this history: Had been in excellent health until within one week, when he was noticed to have a high fever, and was hoarse, which led to an examination of his mouth and throat. White patches were found in both. It was thought to be thrush, and a wash was improvised. He gradually grew worse until last night, when croup set in. When I saw him he was tossing from side to side, struggling for breath, and clawing at his mouth and neck—coughing almost incessantly. Pulse, 135; temperature, 105+° F.; respiration quick, short, and abdominal. Head very hot; feet and hands cool. There were several patches of diphtheritic membrane on the edges of the tongue. The pharynx was covered solidly as far as could be seen; the physical signs indicated an invasion of the larynx; the nares were completely obstructed. Bowels constipated, urine scant, highly colored, and of 1.024 specific gravity. At no subsequent visit did I have an opportunity of examining his urine. The cervical glands were enlarged and tender.

I gently washed his mouth and throat, as far as possible, with a five per cent. solution of papoid, which was to be repeated every hour, if awake; if asleep, not to be disturbed oftener than once in three hours. I ordered a powder of calomel, gr. v., to be followed in six hours by a teaspoonful of castor-oil. He was also to have veratrum viride, gtt. ij., every four hours until the pulse fell to 80; the dose then to be one drop, if that were sufficient to keep the pulse down to that point. I ordered an ointment, thus composed, applied on a flannel covering the chest:

℞.	Pulv. opii	gr. v.
	Pulv. camph	℈ ss.
	Cerum	ʒ iij.

M. To be renewed night and morning.

When the physic shall have acted he is to take quin. sulph., gr. iij.; tr. ferri chlor., gtt. iij., every four hours. Just before leaving him I placed five grains papoid in an insufflator and blew it into the pharynx. On the following day the child seemed much brighter; had been sitting up playing with his toys. The calomel had acted twice during the night, the last operation being decidedly bilious. The tongue and throat were in much better condition, and where the membrane had been thin it had entirely disappeared; the thicker portions had begun to disintegrate and peel off. Pulse, 80; breathing less frequent and easier; the cough, though not so distressing, was still croupous. The nurse informed me that soon after I blew the powder in his throat the day before he threw up great quantities of membrane, when he immediately became quiet and slept sweetly for several hours. He had persistently refused all nourishment until this morning, when he took the mother's breast readily. No change was made in the treatment; the solution of papoid was continued; it was found necessary to make it fresh, as it very soon spoils in hot weather; the throat was not to be swabbed; simply wet with the solution. After the third dose, one drop of the veratrum had been found sufficient to control the pulse.

August 12th.—Following the advice of an officious neighbor, sulphur had been burned in the room last night, and the little patient had contracted a fresh cold, and was much worse this morning. Pulse, 130; breathing labored; croup worse, if possible; restless, and clawing at his mouth and neck; his feet and his legs, to his knees, cold; features pinched; the membrane had fully re-established itself. The nurse had increased the veratrum to gtt. ij., without any sensible effect on the pulse-rate. I ordered it increased to four drops, if so much were necessary; the papoid to be used by insufflation. If there was any trouble in expelling the loosened membrane, he was to be given hyd. sulph. flav., gr. v., to produce emesis. In addition to the quinine and iron, he was to have alcohol, f. ʒ j., every three or four hours. At bed-time he was to have ol. ricini, ʒ j.; ol. terebinth., gtt. v.

August 13th.—Much improved; sitting up playing; has taken beef-tea, a soft-boiled egg, and nurses readily. Pulse, 78; breathes easily, except after a fit of coughing, when he becomes distressed and fretful; has had a choking spell during the night, when he was given the turpeth mineral; he vomited freely, quantities of membrane being ejected, some pieces being figured. On examining the throat only occasional patches were seen, but when the membrane had peeled off the mucous membrane seemed very much inflamed and disposed to bleed. I was assured that no force had been used in its removal. After each insufflation of the papoid he had gagged severely and threw up great quantities of membrane. I discontinued the papoid, and substituted what had become almost a standard wash with me:

℞.	Pinus canadensis	gtt. xx.
	Bromo-chloral	f. ʒ j.
	Pot. chlor	ʒ j.
	Aqua dest	f. ℥ ij.

M. Continue quinine, iron, and alcohol. Veratrum, gtt. ij., t.i.d., if necessary.

Did not see him again until August 16th. He was then convalescing nicely, though when he coughed there was still the metallic ring. The quinine and iron to be kept up for a week or ten days. Ordered flannel clothing. Discharged the case.

I did not isolate the other children of the family—never do—and no other case occurred in the family. The neighbors' children came and went at will, and there has been no other case in that immediate neighborhood. I will state that this is the first case where I have used veratrum viride as the basis of treatment. It would be difficult for me to decide with which I was more pleased in this case, the papoid or veratrum viride. The other seven cases treated with papoid were mild. They were seen on the first appearance of the disease. The papoid very certainly dissolves the membrane quickly, if not *too* quickly sometimes, as I think was the case in the above instance. Of course, my experience with the drug is not sufficient to establish its reputation; hence this report, in order that it may be added to the cases of other experimenters.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

Published by

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place

New York, October 13, 1888.

THE MODERN THEORY OF THE PATHOLOGY AND TREATMENT OF URÆMIA.

Uræmia is a morbid state caused by the accumulation in the body of poisonous products that should be eliminated by the kidneys. So far, all pathologists are agreed. The question has been, and still is, what are these non-eliminated substances? The idea that urea, or its decomposition-products the ammonia salts, cause uræmia, has long been abandoned. The real nature of the poisons, it is agreed, varies in different cases. Recent investigations have given us some truer notions of what they are. The discoveries of Pouchet, Gautier. Feltz and Ritter, and of Bouchard, have been of most value in this line, and Dr. William Carter, in his recent Bradshaw lecture on uræmia, has given an interesting *résumé* of their work.

Pouchet and Gautier have found that poisonous alkaloids are formed by the normal metabolism of the body, and are eliminated rapidly by the kidneys.

Feltz and Ritter have shown that the potassic salts were the most poisonous constituents of the urine. Several observers have proved that urea, though not seriously toxic, can exert some injurious effect on the system.

Bouchard finally has analyzed the different sources of toxicity of the urine, showing their relative harmfulness and also the different ways in which these noxious constituents vary.

The sources of toxicity, says Bouchard, are fourfold—namely, (1) aliments, and more especially their potassium compounds; (2) the absorbed soluble products of intestinal putrefactions; (3) secretions such as the bile, saliva, etc.; (4) tissue disintegrations. Between their several sites of origin within the body, or of their introduction into it from without, and the kidneys, their common site of exit, these traverse the blood, and, if not removed from it with rapidity, poison the tissues. Those that are taken up from any portion of the alimentary canal undergo the modifying influence of the liver, an influence now proved in many and different ways to be of the utmost use in protecting against auto-infection.

By careful injections into the veins of different animals, Bouchard established such facts as the following—namely, that the urine secreted during the night differs from that of the day not only in the degree but in the nature of its toxicity, the former being mainly convulsive in its action, the latter soporific or coma-producing; that that of one part of the day differs from that of another; that the night urine, though specifically heavier, is less poisonous than that of the day; that hard work in the open air markedly diminishes the toxicity, while a mere passing indisposition, indicated by no more serious symptoms than a transient feeling of weariness, markedly increases it; that, within the limits of ordinary health, it varies with the degree of cerebral activity, the presence or absence of constipation, and innumerable other circumstances until lately thought to be of little importance; that the several constituents are not only different from, but to some extent antagonistic to each other; and so on. Furthermore, by comparative experiments on animals, with urines in their natural condition and decolorized by animal charcoal respectively, by injecting at different times aqueous solutions of those portions of the dry residue of evaporated urine that were severally soluble and insoluble in alcohol, and by employing first one and then another definite constituent, such as urea or the potassium compounds, and observing their physiological effects, Bouchard determined the presence of seven distinct toxic substances combined together in the most variable proportions under different circumstances, of which two were convulsivant (one of the two being either the coloring matter or contained in it), one (probably urea) diuretic, one narcotic, one sialagogue, one pupil-contracting, and one temperature-reducing. These could not all be isolated, and their chemical composition determined; yet the conclusions seemed inevitable from the methods of experimentation adopted.

Many of the foregoing facts we have already presented to our readers, but they will certainly bear reiteration. Bouchard gives an approximate estimate of the importance of the different toxic constituents of the urine. Thus he assigns one-ninth to the urea, two-fifths to those substances (including the coloring matter) that are fixed by animal charcoal, a very small but unmeasured fraction to ammonia or its compounds, and the remainder to the mineral constituents, at the head of which stand potassium salts. In other words, the main causes of uræmia are the pigment metabolites, the products of intestinal fermentation, and the potassic salts.

The practical deductions from these new views of the nature of uræmia are in the main confirmatory of the value of ordinary methods of treatment in uræmia. Purgation, diaphoresis, blood-letting, diuretics, are still rationally indicated.

But, besides this, new principles are suggested—the urine is less toxic when intestinal putrefaction is diminished. Hence intestinal antisepsis, by means of naphthaline, iodol, animal charcoal, and milk-diet, is indicated.

The potassic salts being poisonous, the iodide of sodium rather than of potassium may be tried. Muscular exercise and plenty of oxygen lessen urinary toxicity, hence Jaccoud's treatment of Bright's disease by inhalations of oxygen in doses of ten litres three times daily.

Compressed air may, it is thought, be found of value.

The use of vaso-dilators, like nitro-glycerine, has been frequently shown to be of value in helping to eliminate toxic products and in relieving the vascular spasm which their presence in the blood produces.

To sum up, the modern principles of treating uræmia, as set forth by Bouchard, are: "1. In cutting off one or other of the urinary poisons at their source, now that we know to some extent what these poisons consist of, and whence they are derived. Under this head we recognize the great importance (*a*) of limiting potassium salts both in food and in medicine; (*b*) of employing the simplest and most easily assimilated diet, such as milk; (*c*) of bowel disinfection; (*d*) of maintaining at its best the functional activity of the liver; (*e*) of care in the nature of nutrient enemata, when these are required. 2. In directly or indirectly withdrawing or diluting the poison by (*a*) venesection, (*b*) purging, (*c*) sweating, and (*d*) transfusion. 3. In burning up the poison by (*a*) active exercise, and (*b*) the administration of oxygen or oxidizers. 4. In antagonizing the poison, or at least overcoming special symptoms."

THE STATE MEDICAL ASSOCIATION.

THE meeting of the New York State Medical Association this week was an interesting occasion. The attendance was good, and the programme of work was laid out with skill. The Association meetings furnish an excellent opportunity for the country practitioner to visit the city, and combine instruction with a few days of agreeable recreation. We see in its meetings the curious spectacle of the country physician reading papers in the metropolis, while at the gatherings of the State Society the city physician exhibits his attainments in the provinces. On the whole, the contributions of the general practitioner have quite as much of practical interest, while they are refreshingly devoid of any suggestion of self-seeking or specialistical advertisement.

The State Association has quite lost all excuse for existence, so far as ethical matters go. But it is filling a useful purpose in bringing some of the bone and sinew of the profession into the city once a year.

A NEW CAUSE FOR LEAD-POISONING.

A NEW cause for lead-poisoning, which has recently been discovered by Dr. H. C. H. Herold, of Newark, N. J., appears to demand the immediate attention of the profession on account of its wide-spread influence—Dr. Herold having had no less than fifty cases within his own practice during the last six months.

The symptoms observed in these cases were, blue line on gums, constipation, colicky pains, more or less nausea and vomiting, and occasionally paralysis affecting certain muscles. These symptoms clearly pointed to lead-poisoning, but as none of the patients were engaged in any business likely to occasion such a trouble, the cause appeared inexplicable.

Other medical practitioners in Newark reporting similar cases, and the same mystery respecting their origin, Dr. Herold determined to solve the question, and first directed his attention to the nature of the drinks the patients had been in the habit of taking previous to the attacks of lead-poisoning. By a carefuly inquiry into the history of each case, he found that they were all great soda-water drinkers, using that contained in the usual five-cent patent-stopper bottles. Dr. Herold then began an exhaustive chemical examination of this form of aërated waters, which occupied two months of his time, although ably assisted by his brother, Dr. Henry T. Herold. The result clearly demonstrated that all these cases of lead-poisoning were due to drinking this acidulated soda-water, for an examination of all samples proved the existence of lead in sufficient quantities to cause the poisoning in question.

To prove that the presence of lead in this soda-water was not due to accidental causes, such as cleaning bottles with lead-shot, etc., Dr. Herold purchased several dozen new bottles, and had them filled with water which had been charged with pure carbonic-acid gas. With one dozen, aqueduct water was used, and one dozen with distilled water. The stoppers were allowed to remain in contact with the soda-water for only two days, and then chemically examined. The result proved that the aqueduct water then contained .39 grain of metallic lead per dozen bottles, and the distilled water contained .46 grain of metallic lead in the same quantity.

Dr. Herold next directed his attention to the stoppers, and found two kinds on the market; one, with the maker's name stamped thereon, proved to contain, by actual analysis, 42.4 per cent. lead, while an unstamped variety contained 83.6 per cent., or more than four-fifths of lead. Probably the latter form, being the cheapest, is that in common use.

Under these circumstances the chemical result is obvious; for when the soda-water is brought in contact with the stopper, the excess of carbonic acid acting upon it forms an insoluble carbonate of lead. This fact can be demonstrated by anyone who cares to make the experiment.

Now the action of the carbonic acid continues, and redissolves the carbonate of lead, and thus what was at first a harmless carbonate becomes bi-carbonate of lead. This is an accumulative poison, and, if taken into the system even in the quantity contained in one or a few bottles daily, of soda-water impregnated with it, would soon produce marked symptoms of lead-poisoning.

It is possible that the publication of these interesting facts may explain many obscure and mysterious cases of colic which have hitherto been unexplainable, and Dr. Herold's investigation should lead to the abolition of all lead-fittings to soda-water bottle fittings, and to pipes in stationary soda-water apparatus; for undoubtedly the presence of this metal in such positions is a grave source of danger to public health.

THE PHONOGRAPH AS AN INSTRUMENT OF PRECISION.

IT seems not unlikely that the recently perfected invention of Mr. Edison will be of practical value in medical work. It has already been used to record abnormal heart and lung sounds, and reproduce them with almost startling accuracy. If its use can be supplemented by that of the megaphone, whereby recorded sounds can be reproduced with increased intensity, a new system of clinical teaching may be inaugurated. Instead of the professor in the amphitheatre telling the class what he himself hears, all present may be able to hear for themselves. The great trouble with describing physical signs, so as to make them intelligent to another, comes not from a lack of classification, but of minor descriptive terms. If anything, our system of classification is too complicated as it is. But we cannot express with accuracy those slight differences of character which, as physical diagnosticians, we easily recognize with the ear.

Dr. William Porter, of St. Louis, has already made some practical observations in this field. He finds that not only are different voice sounds preserved distinctly, but also that, by attaching an ordinary stethoscope to the phonograph, some of the cardiac sounds could be easily recognized after they had been recorded by the new invention. The murmur of a case of mitral insufficiency was especially well reproduced. He found that normal cardiac sounds were too soft for a perfect record and reproduction. He believes, however, that even this can be done as the machine is gradually perfected and made more delicate.

The wax cylinders on which the imprint is made are not expensive. They will hold about two thousand words, and cost five cents each.

When the phonograph was first presented to the public the paragraphists all had their turn on the humorous possibilities of the machine. Confined to a medical sphere, it must be conceded that they are unique, even startling. We may be able to buy cylinders of cardiac murmurs, aneurismal bruits, fœtal heart sounds, etc., at "list price, twenty per cent. off," just as we now buy charts, manikins, and models. This new class of merchandise will certainly prove a great boon to country medical colleges where clinical material is scarce. If a physician appointed to read a paper before any of the societies should be unable to be present, he can send down his cylinders to be placed in the society's phonograph, and thus his contribution be presented to the members. For, of course, the new machines will eventually be as common as microscopes are now.

THE SENSATIONS OF THE DYING.

The subjective side of disease is one which physicians hear much of, but generally with some impatience. Those feelings experienced by the patient which help in forming a diagnosis, or in modifying treatment, cannot of course be ignored. But the wide range of emotion which the consciousness of a fell disease may excite is something which only the most patient and sympathetic physician can find time to study.

For this reason we would advise everyone to read that remarkable work of Tolstöi's, "The Death of Ivan Iliitch." It is a description, most intense and realistic, of the thoughts and emotions of a man dying of a progressively fatal and painful disease. This disease is the somewhat fantastic, and in the connection impossible, one of "dislocated spleen." The diagnosis, however, is of small moment. The feelings of Iliitch as he gradually realizes that he is in the grasp of a mortal malady; the "pain in the side," the "bitter taste in the mouth," which continually recur to choke out hope and remind him of his inevitable fate; the terrors that at times come over him, his revolt and bitterness over the fact that he must die, his constantly renewed hope of life as constantly destroyed, his curious relations with his worldly wife and daughter, and the final death-scene, are all drawn with a marvellous power. Few can read such a work without feeling new sensations and keener sympathies with those afflicted with a mortal disease.

To be sure, physicians who have dealt for years with sickness and death in all its phases will not agree that Tolstöi's story has general and frequent applications. Death-beds are rarely painful, and even those who have a fatal disorder seem to acquire with it an indifference to or disbelief in their future which prevents any keen suffering. Yet, in some degree, in some persons the subjective side of disease, as portrayed by the Russian writer, does exist, and it is a service to science as well as to literature to have it so vividly and tragically described as has been done.

Tolstöi's views of science and of physicians are, as is known, by no means sympathetic or appreciative, and his description of Iliitch's consultation with an eminent physician bears with it some instructive truth. "It was just as he had expected, he had to wait, and then he saw the doctor, who displayed the stiff professional manners which he knew so well in himself as a magistrate. There were the little thumps, the questions which called forth stereotyped replies scarcely heard, the examination with the stethoscope and the air of importance conveying the idea that the patient had nothing to do with the matter. 'We are going to make it all clear,' the doctor replied; 'we know everything beforehand, and how to set to work; always in the same fashion, no matter what may be your temperament.' Ivan Iliitch could have fancied himself in court. The airs he assumed toward the prisoners in the dock were similar to those which the doctor assumed toward his patients.

"What the doctor said was this: 'This and that in you denote that and this; but should our suppositions not be confirmed, then, after such and such investigations, we must conclude this and that, and if we conclude this and that, then,' etc.

"The only interest Ivan Iliitch felt was in one point—was his condition serious or not? But the doctor paid no heed to such an ill-timed inquiry. From a professional point of view it was an idle question, and unworthy of discussion. As for an exact diagnosis, the complaint, so the doctor said, was a displaced spleen, or chronic catarrh, or an affection of the pylorus. But as to whether Ivan Iliitch's life were in danger, not a word."

Such scenes apply better to the profession in Europe than to that in republican America. The satire is a keen one upon the tendency (on the whole a good one) to examine the body as if it were a machine or a chemical mixture.

PHTHISIS AND THE USE OF ALCOHOL.

THE question whether the use of alcohol has a tendency to prevent the development of phthisis is still a mooted one.

The older writers, such as Magnus, Huss, Johnson, and Leudet, thought that it not only did prevent tuberculosis, but even assisted in arresting the progress of the disease when present. Later observers have taken a somewhat different view. Recently Dr. Alison, in an article in the *Archives Générales de Médecine*, September, 1888, presents the results of his studies of this question among persons living in rural districts, where the history of each case could be followed up for a long time, and in great detail. Among fifty-eight cases of phthisis thus examined he found eighteen, or about one-third, who had been for years excessive indulgers in alcohol. Thirteen of these possessed no hereditary taint whatever, nor were any evidences of contagion discovered. They had all given signs of alcoholism before the phthisis developed. They drank from one to three litres of beer or wine a day, or from one to three litres of brandy a week.

Dr. Alison thinks that the alcohol, in being eliminated by the lungs, causes a congestion and irritation of the bronchial membranes, thus affording a good nidus for the development of the bacillus tuberculosis. He further shows by other statistics that alcoholic cirrhosis of the liver is a comparatively rare disease in the country, even among hard drinkers. This observation will not be disputed.

Neither need there be any doubt that the prolonged excessive use of alcohol, by lowering vitality, may induce phthisis The important question, after all, is whether the moderate use of alcohol favors tuberculosis, or the contrary. We believe it will generally be admitted that, on the whole, such use of alcohol is beneficial to persons having the disease. That its moderate use among persons of phthisical tendency is beneficial or prophylactic is another question, which can hardly be as yet answered. Probably the influence of race, climate, and individual predisposition must here be taken into account.

HOW SHALL THE DOCTOR DISINFECT HIS INSTRUMENTS?

Dr. Hugo Davidson has been making some experiments in the Hygienic Institute at Berlin, in order to find a simple and practicable way of disinfecting instruments. Recent observations show more and more plainly that wounds become infected not so much through the air as through micro-organisms upon the patient's skin and upon the doctor's hands and instruments. The best methods of cleaning the skin and hands are pretty well known, and have been described in these columns. For testing the question of the sterility of instruments, Davidson used the anthrax bacilli, as being the most resistant to disinfectants. He found that the best and simplest process was to boil the instruments for five minutes. A water-bath for this purpose can, he says, be easily obtained and used. It must be covered and all the water must boil, *i.e.*, it must be heated to 212° F. throughout.

His method is to wash the instruments after use in cold water, place them in a water-bath, boil them, wipe them with a sterilized cloth, and place them away for use. By taking these precautions, he can operate safely without disinfecting fluids. He denies that the hot water in any way injures the edge of the instruments.

The method, it seems, is not entirely free from objections, since it would exclude all instruments made of hard rubber.

THE UNION OF MEDICAL SCHOOLS WITH UNIVERSITIES.

The September number of the *New Englander* contains the address delivered in June last, by Professor William H. Welch, now of Baltimore, but formerly of New York, before the Yale Medical School. He spoke especially of the advantages to be secured from a union of such schools with universities, but his address, as we come to peruse it carefully, contains no less valuable suggestions concerning American medical education in general, the history of its past, the promises of its present, and the hope of its future.

He alludes to the old schools at Alexandria and other ancient cities as historical evidence in favor of the main proposition, and comes to the interesting inquiry "What does the present state of medical education and science teach as to the best system of medical education?"

The advanced position of Germany to-day in medical teaching is owing, he argues, to the fact that medicine is there taught "only as a department of a university. Independent medical schools do not exist there. Something more than a feeling of piety has preserved the historic association of the medical with the other faculties."

It is true that somewhat different academic conditions exist on this side of the Atlantic. We have had our ideals, but our newness, geographically and politically, and our poverty have prevented our attainment of them; but we shall be wise to heed the example of older countries in educational matters and methods. This integral relation of the medical with the other faculties has come only from the conviction of its necessity in order to secure the best results.

What now, he asks, are the specific advantages of the proposed union? "In the first place, this system may be expected to maintain the proper balance between purely technical training in the medical art and cultivation of the medical sciences upon which this training should be based; or, to express the same idea more intelligibly, although in somewhat crude and much-abused terms, between the practical and the scientific side of medicine." Anatomy is to be coupled with embryology and comparative zoölogy. Physiology is based upon special application of physics and chemistry, and upon these, together with pathology, is the true system of medical education to be based.

We live in such a practical time that we are apt to forget its relation to that which is intellectual and spiritual. This latter idea has always been kept alive by the university system, and it forms a most important part of character. Hence in universities the practical part of medicine will be ennobled and developed by the intellectual atmosphere of the place.

Again, we are told, university endowment offers greater encouragement of research and the development of original work. The great discoveries of scientific medicine during the last decade have occurred under university auspices.

Finally, economy of organization results from this ideal union. This union must be in fact, and not merely in name. Right here comes the imperfection in this particular with our own local schools. Two of them are allied nominally with universities, but this alliance runs little further than the appearance of some of the same names on two different trustee-lists. The universities might be in Alaska for all the good that their endowments do the medical students. That public attention is being drawn to the matter of medical education is attested by the material prosperity of our schools. The magnificent donations of the last few years mean, however, more than this. They mean an awakening of the public conscience to the fact that the profession, in its furtherance of preventive medicine, is the guardian of their firesides no less than civil authority. But, as waves of further prosperity roll in, may we not plead for a further extension of the union between medical school and university, so that the combined influence of the two may graduate physicians who shall be alike skilful physicians and soulful men.

News of the Week.

No Yellow Fever in Atlanta, Ga.—Dr. James B. Baird, M.D., Secretary of the Board of Health of the City of Atlanta, writes: "In The Medical Record of the 22d ult. it is stated that yellow fever has appeared at Atlanta, Ga. In fact, there has not been a case of yellow fever in this city for many years, and no case has ever developed here except, rarely, among refugees who have been exposed to the disease before leaving infected places during former epidemics."

A Correction.—The *Boston Medical and Surgical Journal*, from which an extract was quoted by The Medical Record bearing on the composition of several artificial foods, publishes a correction based upon the analyses of Professors Elwyn Waller and A. A. Breneman regarding Reed & Carnick's soluble food, to the effect that 38.26 per cent. of the albuminoids which it contains are in soluble form, that no "hard unchanged particles of casein" were found, that the casein is partially rendered soluble by the action of the digestive ferment, that the proportion of albuminoids is limited only by the quantity which can be kept unchanged in solution, that sixteen per cent. of alcohol is necessary to prevent decomposition of the albuminoids, and that no greater than three per cent. of these can be held in solution in this liquid. We publish the correction from the same source as the original quotation as an act of justice to all concerned, regretting that we, in common with our Boston contemporary, were in any manner misled by what appeared to be a well-authenticated official report.

Death of Dr. Henry Rolando, of Baltimore, Md.—Dr. Henry Rolando, aged twenty-seven, died, October 4, 1888, at his home, No. 1309 Park Avenue, Baltimore, after an illness of some weeks. He was well known in this city, and gave promise of becoming prominent in the medical profession. Graduating in 1881 at the Johns Hopkins University, he studied medicine at the University of Maryland in 1883. During 1883–85 he was resident physician at the Presbyterian Hospital, New York, and for the past two years had been practising his profession in this city. He was single, and was the nephew of Dr. Riggan Buckler.

The Virginia State Medical Society meets at Norfolk on October 23d.

Homicidal Paranoia in Texas.—In 1885 there was a series of murders and assassinations of women which extended at intervals throughout the year. Eight women in all were killed, including two white married women. The others were colored women and girls. These murders have never been explained. The assassin left no trace whatever to identify him. There was a fearful similarity among all these murders—nearly all were killed about midnight, and usually within a few days of full-moon nights. All of the victims were struck with some sharp instrument about the head, and on the same side of the head. All were slain in profound silence, even persons in an adjoining room hearing nothing. The bodies were all found in the same position. All were dragged out into the back yard.

The State Board of Lunacy and Charity of Massachusetts seems to be in continual trouble. In the vortex of this is the figure of a Mr. F. B. Sanborn, the Secretary. Five years ago the Governor of Massachusetts tried to remove him, but failed. Now the Board itself has undertaken the same task.

The Medical Profession of Memphis is suffering from the taunts of the press because certain members in authority thought that a case of drunkenness ending in a bilious attack was suspiciously like yellow fever. A general panic followed and lasted twenty-four hours, then the whole country knew that Mr. Binford, of Memphis, had been intoxicated. Our esteemed contemporary, the *Memphis Medical Monthly*, is taking the matter too deeply to heart, and publishes a number of apologetic, defensive, and argumentative editorials to show that the local profession was not to blame. Two columns of "taunts" from the press are also printed, doubtless for their educational effect upon the city's medical talent. Here are some specimens.

Citizen: Hello, Doc., have you seen Mike?

Doctor: What Mike?

Citizen: Microbe; he is looking for you.

A few barkeepers who are judges of "suspicious cases" are wanted on the Citizens' Committee and the Board of Health.—*Ledger.*

Col. R. Dudley Frayser stated to a *Ledger* reporter this morning that a good barkeeper and a first-class judge of liquors should be added to the Board of Health to complete the outfit.—*Ibid.*

Col. Bob Leech is not much scared. He allowed a reporter of the *Ledger* to look at the opening of a letter to his daughter, in which he said: "We have had one grand 'surprise'—a drunk in Memphis. We have had nothing of the kind in the last decade, and our physicians were at sea, but some good coffee and 'steamboat talk' brought him around all right."—*Ibid.*

Mayor Hewitt and our Insane Asylums.—Mr. Hewitt gives a graphic account of the condition of affairs in our city lunatic asylums, showing the results when an independent mayor attacks abuses due to political management. He says: "When I entered office I went through the Charity Department Institutions, and I found a terrible state of affairs respecting cooking in the insane asylum. The means of cooking was inadequate, and the cooks employed were worthless. An outrage was doing to the poor insane. I spoke strongly about the matter to Dr. Macdonald, but he proved that ever since 1875 he had been asking for the means to provide his patients with proper food, and that his appeals had been disregarded. I knew that the taxpayers of New York were not mean, that they did not want to save money in that way. Money was appropriated for a cook house and for the reformation of the cook's staff. This picture shows the result—a fine building and a party of lunatics who have been taught to cook well and are benefited by having something to do. And the cost of cooking is less than when methods were followed that aroused a sense of disgust in everybody who saw them."

Surgical Evisceration.—It is stated that a surgeon of this city recently successfully removed the spleen and one of the kidneys of a patient.

A New Hospital.—The corner-stone of the new St. Joseph's Hospital at Yonkers was laid by Archbishop Corrigan on Sunday, September 23d. The site of the hospital is on a high cliff overlooking the Hudson, and the buildings will be substantial and thoroughly equipped. The estimated cost is $140,000.

The Professorship of Clinical Medicine at Johns Hopkins University.—Dr. William Osler, Professor of Clinical Medicine in the University of Pennsylvania, has been appointed physician to the Johns Hopkins Hospital, and Professor of Medicine in the Johns Hopkins University. Dr. Osler took his degree in the McGill University, Montreal. He subsequently studied in London, Berlin, and Vienna, and in 1885 was appointed Gulstonian Lecturer in the Royal College of Physicians, London, and in 1886 Cartwright Lecturer in the College of Physicians and Surgeons, New York.

Half a Million for Yellow Fever Camps.—A bill has been favorably reported from the Committee to the House of Representatives, providing for the appropriation of $500,000, to be expended in establishing camps for yellow fever refugees.

The Yellow Fever Epidemic at Jacksonville has shown slight symptoms of abating in the past week. The mortality, however, is now very low, and the virulence of the disease is lessened. The total number of cases, up to October 10th, was 3,319; the deaths, 299.

Re-establishing the National Board of Health.—The question of re-establishing the National Board of Health, or a body having similar powers, is being agitated in the Southern papers. The Memphis *Appeal*, in a recent issue, says, in double-leaded type: "The request forwarded to Senator Harris and Representative Phelan yesterday by President Hadden, representing the taxing district; President Martin, of the Merchants' Exchange, and President Suggs, of the Cotton Exchange, and other gentlemen, for the re-establishment of the National Board of Health, was a timely movement that we feel sure will have the immediate attention of our representatives. The contentions and confusions that have grown out of the clashings and local boards, and the demands of the people everywhere for non-intercourse, make it plainer than ever before that a National Board of Health, or a National Bureau of Health, is a necessity to the maintenance of the public health, the prevention of the spread of disease and panic, and the saving of life and property."

Professional Certificate Signers. — One often wonders where all the doctors come from who sign certificates of proprietary and secret remedies. An item in the papers shows the residence and methods of one of this class. Dr. Willard H. Morse, an alleged chemical expert of Westfield, N. J., sold his so-called analyses for ten dollars upward. He was recently arrested by Anthony Comstock's society for fraudulent use of the mails. He confessed everything, and pleaded ignorance of the law in extenuation. He scanned the medical and pharmacal journals, and when a new advertisement appeared he sent the manufacturer a very critical analysis to insure payment for a laudatory one.

Society Reports.

NEW YORK STATE MEDICAL ASSOCIATION.

Fifth Annual Meeting, held at the Hotel Brunswick, New York, October 9, 10, *and* 11, 1888.

October 9th—First Day—Morning Session.

Dr. John Cronyn, President, called the meeting to order at 10.15 a.m.

After standing committees had made their reports, The President read his address, taking for his subject

THE MEDICAL PROFESSION AND THE PUBLIC.

Quoting a lay writer, he said what the public needed to place it in more harmonious relations with the profession was not to be more thoroughly instructed in medical books, but to be taught to distinguish between the true and the false, between the charlatan and the honest, conscientious physician. This task would take more than one generation, and could be accomplished through the influence of the profession, but it must be confessed physicians too often encouraged the ignorance which they ought to enlighten.

The physician was born, not made. Genius, ambition, and love of profession could not make one a physician if the quality of the genius were not medical. The physician required swiftness of action, power of immediate perception, ready analysis, and induction; he should have reverence for the possibilities of his profession. Without these natural qualifications medical education would not make of one a successful practitioner, nor place the profession, as a whole, in its best light before the public.

Dr. Oliver P. Hubbard read the history of

A CASE OF ANÆSTHESIA BY THE INHALATION OF NITROUS OXIDE,

supposed to be the first on record.

The case occurred, November 13, 1821, at Rome, N. Y., in a young man who was found in a room, completely anæsthetic from nitrous oxide which he had turned on from an apparatus in the use of a lecturer. The patient was removed to another room, and recovered.

Dr. George E. Fell read a paper entitled

FORCED RESPIRATION: HISTORY, APPARATUS, AND REPORT OF SIX CASES—EFFECTS OF, ON NARCOTIZED SUBJECTS; ADAPTABILITY OF, IN CASES OF DROWNING OR SHOCK.

He used the term forced respiration in contradistinction to that of artificial respiration. His first case was that of a man who in July, 1887, had, after drinking, taken twenty grains of morphine. The stomach was emptied, belladonna and atropia were administered, the patient was moved about, but opium-narcotism grew more profound, and forced respiration was resorted to. At this time there was venous congestion of the face, and there was not the slightest effort at respiration on the part of the muscles. After the trachea had been opened, and forced respiration by the bellows had been instituted, the patient soon began to make movements which caused disturbance of the tracheotomy tube and hemorrhage, and thereby endangered life. After forced respiration had been continued two hours and a half the patient was allowed to breath for himself. Delirium tremens afterward complicated the case, but the patient recovered. The second case which he cited did not occur in his own practice, but in Germany.

In the third case Sylvester's method of artificial respiration had been continued some hours before Dr. Fell arrived to employ forced respiration. The patient was unable to breath for himself for over fourteen hours, and it was necessary to continue forced respiration nineteen or twenty hours, and at intervals for some hours longer. Recovery finally took place.

In the fourth case the man had attempted suicide by cutting his trachea, his arm, and by taking a large quantity of laudanum. Several physicians saw him at the hotel before Dr. Fell was sent for, all of whom pronounced his case hopeless, and the coroner ordered a coffin. Forced respiration was established through the tracheal wound and the patient was soon partially resuscitated, but his vitality was so low that this means also would have failed to save life had they not performed transfusion with a prepared liquid. The loss of blood from self-inflicted wounds had been great. Some abscesses developed at points of hypodermic medication, which prolonged the patient's convalescence.

In the three cases recited there could be no question of a fatal result had not forced respiration been resorted to.

Case V. occurred in a Buffalo hospital and was treated by the house-surgeon. It also was from opium-poisoning. Life was prolonged fourteen hours by forced respiration, when the patient succumbed.

Case VI. was that of a child, aged eighteen days, which had by mistake been given one grain of sulphate of morphine. Six hours later forced inspiration was begun, and hopes were even entertained of yet saving life, but four hours later the heart failed. The author thought that had forced inspiration been begun two hours sooner the patient might have been saved. Another case in which he tried forced respiration was that of a still-born child. It was not brought to life, although the method was applicable.

Artificial respiration was, in the class of cases under consideration, carried on at the expense of the patient's energy, as well as that of the physician. Not so with forced inspiration. He thought the latter could be employed with advantage in drowning, and also in shock, although he had not had an opportunity to try it. The action of the apparatus was demonstrated, and it was seen to be equally applicable in adults and infants. Three motions of the bellows represented one inspiration, and three one expiration. Its action was continuous, the air, during three movements, being forced into the lung, and during the next three escaping externally through a valve, during which time the air within the lung also escaped. The air could be warmed or medicated with ease.

AFTERNOON SESSION.

DR. **ALFRED L. CARROLL** read a paper introducing the

DISCUSSION ON NOSOGRAPHY.

That there was need of a proper classification of diseases must be evident to every teacher and practitioner of medicine. Under the present method, or rather, lack of method, lesions and symptoms, causes and consequences were so interchangeably confused as to retard scientific education. Until our knowledge of pathology should be completed, any classification must necessarily be provisional; but as our knowledge extended regarding a given disease, its name should be changed and a new one be used based on a definite classification. In speaking of classification based on anatomy, the latter term comprised action, growth, microscopical structure, and chemical constitution of the various component parts of the body in both normal and abnormal conditions. In this sense it would be impossible to think of any alteration or derangement which could not find a suitable place, or any clinical phenomenon which could not be satisfactorily registered if it were satisfactorily investigated. For the intercommunication of ideas between different nations it was necessary that names be derived from universal and intelligent roots. Hence Greek and Latin must supplant vernacular terms.

The proper place for the microbes had not been determined with certainty, but he thought the impression was gaining ground that the part which they played in the production of disease had been overestimated. As to the place to be assigned to ptomaïnes and leucomaïnes, there was alleged evidence, at least, that a few of the latter were mutually antagonistic. Of the nature and mode of operation of various extractives we could yet but surmise.

DR. **E. G. JANEWAY** discussed the question,

WHAT ARE THE ADVANTAGES OF A NOSOGRAPHICAL SYSTEM BASED UPON ANATOMY?

His remarks were submitted in writing, for he had on study come to the conclusion that at present it was not practical to found a system of nosography on anatomy alone. Take, for instance, typhoid and typhus fever; could there be given a name on an anatomical basis? He thought not. If the disease were dependent upon a parasite, as trichiniasis, an attempt to name it on an anatomical basis would at once cause a confusion of anatomy and etiology. Difficulty would especially become manifest in trying to classify nervous affections on an anatomical basis. The term epilepsy meant little except to the one who knew the disease clinically; anatomically it could not be classified. There would be less difficulty in making an anatomical classification and nomenclature of local than of general diseases. What general principles should govern classification and nomenclature, irrespective of their particularization in medicine?

M. L. BRITTON, Ph.D., discussed this subject from the point of view of the botanist, giving the basis of classification and nomenclature in botany.

DR. **E. D. FERGUSON** read a paper entitled

DOES A NOSOGRAPHY BASED UPON ANATOMY AFFORD SATISFACTORY MEANS FOR THE REGISTRATION OF CLINICAL PHENOMENA?

He said the uncertainty of facts had made him charitable of the looseness which prevailed in nomenclature and classification. The meaning of any term whatever would vary more or less according to the mental peculiarity and education of the person using it. The attempt to make a classification or nomenclature need not be postponed until perfection was possible. No word, nor even phrase, could fully describe the disease; it could only imperfectly do so. Some words, when first used, were intended to be descriptive of the thing they represented, but they often continued to be used long after this description had been proven quite false. Proper names of persons were at one time intended largely to be descriptive, but this meaning entirely ceased in after-generations, and it might be a question whether the naming of diseases by numbers would not be less confusing than to employ descriptive terms. While he might criticise Dr. Gouley's classification he was unable to offer a better.

CHARLES RICE, Ph.D., sent a brief communication on ptomaïnes as regular constituents of urine in cystinuria.

DR. **MICHELL**, of Charleston, thought a classification based on anatomy was best and practical, and that the objections offered by Dr. Janeway with reference to typhoid fever, etc., were not insuperable.

DR. **E. M. MOORE** mentioned dropsy, and some other terms formerly employed as designating a presumable disease, while now they were known to represent only a symptom of a disease. Notwithstanding the difficulties in the way, it would be desirable, where possible, to have an anatomical classification, for we then had a solid basis.

DR. **J. W. S. GOULEY** said, with regard to the restrictions which had been placed upon an anatomical classification, that they were not well founded, for the word anatomy was used in its broad sense, and included physiology, bio-chemistry, embryology, etc. We should make all these branches subservient to our nomenclature. It was perfectly possible to make a classification in harmony with whatever part was taken by the ptomaïnes and leucomaïnes.

ELWYN WALLER, Ph.D., discussed the question,

WHAT PLACE IN NOSOGRAPHY SHOULD BE ASSIGNED TO BACTERIA, PTOMAÏNES, LEUCOMAÏNES, AND EXTRACTIVES, RESPECTIVELY; (*a*) FROM A BIO-CHEMICAL, (*b*) FROM A CLINICAL POINT OF VIEW?

DR. **NELSON B. DE SIZER** followed with a paper on the same subject, which he treated in a more or less exhaustive manner. Ptomaïnes, the work-product of microbes, were due mostly to animal decay, less to vegetable decay, and varied in properties almost infinitely, some being virulently poisonous, others only feebly so. Certain ones developed only when decay took place under certain conditions, the germs causing the decomposition requiring a varying life-medium. The products of the same germs might cease to be poisonous when those germs were transferred to a purer water. Certain epidemics of disease were evidently due to ptomaïnes which had their origin in decomposing food. Dr. De Sizer referred to one case, however, in which the poison causing fatal sickness in one family had its origin in canned apricots.

The fact that the bacilli formed a chemical poison and the proof of this theory of the origin of certain diseases, amounted to almost demonstration, although the chemistry was yet imperfect. As to the action of the leucomaïnes, their poisonous influence was readily manifest when the human body failed to throw off its excreta. He quoted approvingly the view that chlorosis might be caused by the absorption of fecal matter.

Dr. Charles W. Brown cited an experiment with the blood of a horse which died of traumatic tetanus. Some injected into a litter of kittens caused all to die with symptoms of tetanus, while the irritation at the point of injection was scarcely perceptible. The cause of death was, perhaps, by ptomaïnes or leucomaïnes introduced with the blood of the horse.

Dr. W. D. Garlock then read a paper entitled,

THE ORIGIN AND MEDICAL TREATMENT OF URIC-ACID CALCULI OF THE KIDNEY.

He said of treatment that it should relate (1) to alimentation; (2) metabolism, including diathesis and excretion; (3) habit of life, climate, occupation, etc.; (4) local disorders leading to production or prevention of excretion of uric acid. These factors had to be kept constantly in mind in the treatment of the uric-acid diathesis and in efforts to remove stone from the kidney by solvent remedies. Moderation in diet was probably of more importance than exclusion of any particular kind of food. He thought a mixed diet was to be preferred. Milk-diet, if it could be maintained a long time, would probably be best of any exclusive diet, and should form an important part of any mixed diet.

The diet in lithiasis should embody in proper amount various albuminous, starchy, and saccharine elements selected from articles most easily digested; the albuminoids should be animal rather than vegetable.

There seemed to be an increasing appreciation of the value of sodium compounds. Anything which had the power to lessen the colloid matter in the pelvis and calices of the kidney would prove prophylactic in high degree. Of all local conditions, catarrh of the pelvis of the kidney, or pyelitis, aided perhaps most in stone-formation, and this was greatly intensified, especially for phosphatic stone, if ammoniacal degeneration supervened.

Evening Session.

Dr. Frederick W. Putnam read a paper entitled

HICCOUGH, WITH NOTES ON TREATMENT.

Hiccough might occur without known cause, or in the course of various diseases. The milder cases occurring in childhood were usually readily relieved by domestic remedies. In other cases the hiccough lasted hours or even years. In one instance the affection continued twenty years, and led the patient's husband to seek a divorce. The paper dealt chiefly with treatment, briefly reviewing the various means of producing relief by diverting the patient's attention, producing a sudden influence upon the nervous system, electricity applied to the diaphragm, the phrenic nerve, etc., or the use of pressure or dry-cups over the phrenic nerve; the value of drugs, such as ipecac., valerian, anæsthetics, etc. If chloroform were used, its influence, he thought, would be greater on the hiccough if it were produced suddenly.

Dr. J. Lewis Smith then read a paper on

DIPHTHERITIC PARALYSIS AND THE TREATMENT OF DIPHTHERIA,

first reviewing the history of diphtheritic paralysis, which, he said, was not described by writers as far back as the sixteenth century. Definite knowledge on the subject began to form about 1855, but the nature of the paralysis, the manner of its occurrence, and its pathology were still undetermined.

The statistics of different writers differed regarding the frequency of the affection, which is to be accounted for by the fact that some epidemics were more severe than others.

The paralysis did not usually begin until the period of pseudo-convalescence, but cases have been recorded in which the paralysis developed as early as the third day. Mild walking cases of diphtheria occurred not infrequently in New York, and the diphtheritic affection might be overlooked until after paralysis developed.

The paralysis was motor and sensory, a fact which should be borne in mind in studying the nature and cause of the affection. The muscles affected atrophied, as in other forms of paralysis. The symptoms varied, of course, with location.

Loss of tendon reflexes, usually preceded other signs of paralysis, and was present in one-third to one-half of all cases.

As to the muscles affected, the velum palati and pharyngeal muscles were most commonly involved, although various muscles of the body might be implicated. The paralysis was never general, but frequently multiple. When the muscles of the heart and lungs became paralyzed death ensued. Post-mortem examinations in these cases had revealed nothing abnormal in the heart's muscle or nerves.

The treatment of diphtheritic paralysis was hygienic and medicinal. He thought galvanism had proved of benefit, as had also strychnine. Perhaps the latter acted as a tonic.

Dr. George E. McDonald read by title

A CASE OF SUPPOSED PARTIAL TWIST OF THE INTESTINES

Dr. E. J. Chapin Minard read a paper entitled

DOES THE MENSTRUAL FLOW ORIGINATE IN THE TUBES?

She had been invited, in August last, to see a case of inverted uterus. When she saw her the patient was menstruating, it being the first time since the birth of a child five months previously. She was nervous and prostrated, the flow was unusually free. The uterus was proved to be inverted, the tubes dragged down in the sac formed by the peritoneal surface of the inverted uterus. The surface of the tumor thus formed was of a dark-red color, studded with points of a darker hue, resembling the tongue of a bad case of scarlet fever, without the creamy coating. From this surface no discharge to speak of could be wiped away, but from the tubes a dark, healthy menstrual flow, non-fibrinous, passed out drop by drop, and when the tubes were pressed upon would form a stream for an instant.

If the menstrual flow did take place from the tubes many things would be explained in gynecology and midwifery which were now dark.

Dr. J. P. Garrish presented a paper, which was read by title, on

THE USE AND ABUSE OF THE FORCEPS IN OBSTETRICS.

Dr. C. A. Leale reported on some specimens of

RASPBERRRY SEEDS MISTAKEN FOR GALLSTONES,

presented at the last annual meeting by Dr. R. H. Sabine, consisting of small, hard, corrugated bodies passed to the amount of half a teaspoonful by a woman, believed to be gallstones, but which proved to be raspberry seeds.

Wednesday, October 10th—Second Day, Morning Session.

ADDRESS ON SURGERY.

Dr. William H. Carmalt, of Connecticut, read the address, choosing for his subject,

REMOVAL OF THE CANCEROUS TONGUE.

The infiltrations of the growth, difficulty of swallowing, the annoyance of dribbling of saliva, fetid breath, more or less frequent attacks of impending suffocation, the consciousness that there was no permanent relief, tended to make the patient's condition wretched, and should induce the surgeon to do all in his power to give temporary relief. The radical operation of extirpation was now the only accepted one in cancer of the tongue. Statistics of the Connecticut State Board of Health gave statistics of 1.227 cases of death from cancer, in 231 of which the site of the disease was unknown. In 12 of the remaining 996 it was located in the tongue. In 3 the sex was not given; in 1 the disease occurred in a female; in 8 in men. Probably the proportion of cancer of the tongue to all cancers was one per cent. The general rule in cancer existed in these cases, that it usually originated at a point of long-continued irritation. The irritation might be due to broken teeth, incrusted teeth, hot pipe-stem, etc. The reader was indebted to Mr. Barker's article for much valuable information on various operations, etc. A simple enumeration of these showed the many and important difficulties which surgeons had encountered in operating. Death after the operation came from one of two causes: from hemorrhage—primary or secondary—or from septic pneumonia. If the patient recovered from the operation death would, of course, finally result from recurrence of the disease in surrounding tissue.

Hemorrhage during the operation was almost entirely under the control of the operator. Skilled assistance was necessary during the operation. Dr. Cormalt would not undertake the operation with cocaine alone, or an anæsthetic, although it had been done. If the artery were tied, it should preferably be done in the digastric triangle. He favored preliminary tracheotomy, to administration of anæsthetic, to prevent blood entering the lungs, etc., and feeding the patient through a stomach-tube. He opposed removal of the diseased mass by ligation, écraseur, and galvano-cautery. With the use of the cautery the slough was long in coming away, and exposed the patient to septic infection from decomposition. After referring to Whitehead's operation by the knife, he described that of Kocher, of Zurich, which Dr. Cormalt adopted in one instance successfully; but the patient exposed himself six weeks later, and contracted pneumonia, from which he died. He did not favor leaving half the tongue, as it was of little use, and one could not say positively that it contained no cancerous infiltration.

Dr. Charles W. Brown then read a paper on

RAILWAY INJURIES.

He gave statistics of two hundred and sixty-five cases which had come under his care. They showed that the appearance of the parts often enabled the experienced railway surgeon to judge of the manner in which the injury had been inflicted; when the hand or fingers were caught between the draw-heads the parts were nearly, if not completely, cut through, and when between the bumpers they were crushed to a pulp, etc. When the wheels passed over a limb it was frequently mashed and torn to pieces, but he had seen many cases in which from one to a dozen wheels of loaded cars had passed over the leg, which had on it a heavy sock, boot leg, and thick trousers, and after removing these the skin was found unbroken, and to a casual observer would not show even a mark of injury; but when the knife was thrust through the limb it collapsed like a broken bubble, all the soft parts, except skin, and the bone reduced to a fluid pulp. Fractures of long bones were very likely to be compound.

Of the 265 cases there were 53 of crushed fingers. or of 80 fingers; 18, crushed forearm, etc.; 19 cases of contused wounds; 61 fractures; 14 scalp wounds; and various other wounds. Amputations were performed on 41 patients, and included the removal of 58 fingers. All the patients on whom amputation was performed, except 4, lived. They were all immediate amputations except two, and the author spoke strongly in favor of the immediate operation. In many cases, by waiting for reaction to take place, the shock already produced by the crushing wound would have added to it mental shock, and in many cases would end in death. If, in place of waiting for reaction, an effort were made by the use of whiskey hypodermatically, artificial heat, and "hot sling" internally, to assist nature in bringing about reaction, which would in nearly every case manifest itself by rapid improvement in circulation, primary amputation under ether would leave a clean stump, and mental anxiety would disappear. The inexperienced surgeon was likely to leave a part that should be removed in his anxiety to save enough skin for flap. He preferred porous dressings not covered by oiled silk.

Dr. Thomas Manley, speaking from experience with injuries inflicted by horse-cars, etc., expressed an opinion against primary amputation. He would not use dressings intended to prevent access of air to the wound, as oiled silk. Children were unfavorable subjects for amputation.

Dr. E. M. Moore cited a case of complete crushing of the arm; the skin, however, not being broken and the vessels remaining intact, amputation was not performed and the arm became useful. Primary amputation was always preferable to secondary. When the limb was badly mangled, do not try to save it; give whiskey, ether, and the knife, replace the mangled limb by a clean amputation-wound, and thus avoid much mental distress and shock in the patient. Bichloride acted not only as an antiseptic, but also as a local anæsthetic.

Dr. J. W. S. Gouley then opened the

DISCUSSION ON TUMORS.

He spoke of the great utility of periodical examinations of the question of tumor-formation in the human body. The term tumor should be used in its sense of a swelling in any part of the body, to the exclusion of inflammatory swellings, etc. Tumors are accordingly divided into four classes, viz.: 1. Neoplasmata; 2. Adenomata; 3. Blastomata; 4. Cystomata. Neoplasma or new formation is applicable to certain benign and to malignant tumors but not to adenomata, granulation-growths, or cysts. The views of Hasse, Cohnheim, and Lancereaux are set forth regarding the genesis of new growths.

Clinical observation, supplemented by microscopical examination, has established the fact that neoplasmata of high organization are benign while those of low organization are malignant, and that the lower the organization the greater the malignancy.

The basis adopted for the nomenclature and classification of tumors is the broad anatomical foundation comprising embryology, physiology, histology, etc.

Degeneration of benign into malignant tumors is admitted and accounted for partly by metaplasis, partly by the independent proliferation of embryonic cells, but it is denied that the whole of a tumor is metamorphosed. for its primary benign elements are traceable in the general mass of disease.

The questions of recurrence and curability of malignant tumors are examined from a pathic as well as from a clinical point of view. Eleven cases are cited in illustration of periods of immunity ranging from seven to forty years from the time of the extirpation of malignant tumors, the average being a fraction over nineteen years. In three of these cases there was no recurrence. In seven cases the disease recurred once in each case as follows: in 8, 8, 16, 20, 25, 30, and 40 years. In one case the disease recurred three times. The first recurrence was twenty years after the operation, the second two years after the second operation, when there followed a period of immunity of twelve years; a small growth then appeared which rendered the fourth operation necessary. The patient was living and well three years after the fourth and thirty-seven years after the original operation.

Three cases are still under observation. In one of these cases there was no recurrence seven years and three months after the operation. In one case the disease recurred in twenty years. when a second operation was performed. There was no further recurrence in three years and eight months. In one case the disease recurred in eight years, when a second operation was performed. Six years and three months afterward there was no sign of further recurrence.

The question, *Are malignant neoplasmata ever cured?* may, then, be answered, first, from a strictly scientific, and, secondly, from a clinical point of view. In the first case the answer will be negative, while in the second case it may be affirmative with qualifications. From a scientific point of view, it cannot be said that malignant neoplasmata are cured– since it is known that their tendency to recur is strong, and that the period of their recurrence is indefinite—if the term cured be used in the sense of restoration of health without limitation so far as the particular disease is concerned. But if, from a clinical point of view, the term cure be used in the sense of temporary restoration of health, so far as the particular disease is concerned, it may then be said that malignant neoplasmata are practically cured, especially when the period of immunity is extended to eight, ten, fifteen, twenty, thirty, or forty years after excision. A reasonable doubt as to accuracy of diagnosis naturally arises when a neoplasma, said to be malignant, is declared cured many years after its ablation, unless its relation come from an experienced clinician and include the statement of a searching microscopical examination of the excised growth by a competent patho-histologist, or unless it be known to have recurred in after-years. In regard to the treatment of malignant tumors, the conclusions of the speaker are as follows:

1. A suspicious neoplasmata, susceptible of excision, cannot be too soon removed. The earlier the operation the greater the chances of prolonged immunity.
2. In the excision of malignant neoplasmata, as much of the neighboring healthy tissues should be sacrificed as is compatible with sound judgment.
3. Immediately after the excision of malignant neoplasmata, careful search should be made for diseased neighboring lymphatic ganglia, all of which should be removed.
4. Excision of multiple malignant neoplasmata is contraindicated, particularly when they invade many lymphatic ganglia, or when they are disseminated in hundreds upon the surface of the body. If, however, there be among them a very large growth seriously interfering with a vital function, the excision of this growth is warranted on account of the temporary benefit that may thus be conferred upon the sufferer.
5. When a malignant growth is in a state of ulceration and this necrotic process and consequent putrescent discharges become a source of exhaustion to the patient, the growth, if accessible, should be forthwith removed. By this means suffering is mitigated and the life of the patient is rendered more tolerable, and may even be prolonged many months.
6. When hemorrhage from a malignant growth threatens life, the diseased mass, if within reach, should be extirpated without delay, to prevent sudden death from a great loss of blood, though the general infection be such as to give the surgeon little hope that the patient will live more than a few weeks.
7. When an ulcerated malignant growth involves a large cutaneous surface, a cutting operation being contraindicated, applications of sundry kinds, such as cataplasms, soothing lotions, deodorizers, etc., should be made, and opiates should be administered in sufficient quantity to mitigate pain and insure sleep.
8. Whenever its locality and other circumstances are favorable, the whole wound resulting from the incision of a malignant neoplasma should be cauterized as freely as the nature of the case will permit.
9. The medicinal treatment of malignant growths has been too generally discarded of late years. This treatment fell into disrepute because of the inconsiderate and extravagant claims made for many so-called specifics, and because it was used as a distinct means of "cure," and not as an adjuvant of surgical treatment. Very much mischief has been the outcome of attempts made to cure malignant tumors exclusively by means of internal medication, which is so delusive as to lead both physician and patient to temporize until it is too late for operative interference. No kind of medicinal agent so administered has ever cured malignant tumors. Nothing short of their extirpation, principally with the aid of the knife, has ever been of any avail, and this mode of treatment often requires to be supplemented by the cautery, and to be employed in an early stage of the disease. Then only are the longest periods of immunity likely to follow, and only as a help to this end is constitutional treatment of any use.

AFTERNOON SESSION.

DISCUSSION ON TUMORS (*continued*).

DR. ALFRED L. CARROLL discussed the question,

WHAT IS THE RATE OF MORTALITY FROM MALIGNANT NEOPLASMATA AS COMPARED WITH OTHER DISEASES?

Statistics should be accepted with care. The best he had bearing on the above question were those of the Health Board of the State of New York, giving the entire mortality in the State for three years as 264,161, and of these cancer was given as the cause in 6,162, being a little more than two and one-third per cent. It was possible some deaths attributed to cancer were due to sarcoma. Probably many deaths due to internal cancer were attributed to other causes. More deaths from cancer occurred in sparsely than thickly settled districts; more in the country than in cities. Possibly this could be accounted for by the fact that in cities surgical interference was earlier and more commonly resorted to.

DR. HERMANN M. BIGGS discussed,

WHAT ARE NEOPLASMATA, AND WHAT ARE THE CHARACTERS WHICH DIFFERENTIATE THEM FROM BLASTOMATA, AND THESE FROM INFLAMMATORY PROCESSES.

Neoplasmata were tumors which tended to persist or increase, independent of the nutrition or organism from which they arose. They often grew quickly when the organism from which they were derived rapidly emaciated. Their growth was not determined or limited by a definite purpose, and the condition of their growth and nutrition was largely independent of those obtaining in the parent organ. In this sense, neoplasmata were parasitic.

The second part of this question was answered by defining blastomata, which were infectious, inflammatory new formations which showed no tendency to persist or increase beyond a certain size. They did not usually pass beyond the stage of granulation-tissue; they soon began to degenerate. Their formation was a conservative process tending to limit the extension and multiplication of the organism which caused their growth. They differed from neoplasmata in that their formation was determined by the action of specific forms of micro-organisms. Blastomata were distinguished from inflammatory processes by their occurrence in the form of minute nodules or tumors, all containing specific forms of micro-organism, by their failure to pass on to fibro-blast stage of development, by their early tendency to degeneration, by their local infectivity, by their tendency to dissemination and reproduction in distant parts. Yet blastomata were essentially inflammatory; they were in reality only inflammatory infective new growth.

Dr. Biggs thought the only rational basis for classifying neoplasmata was that of histogenesis; and the naming of the tumor, if on an ananatomical basis, gave a pretty accurate conception of its relative degree of malignity.

Among objections to the grouping of neoplasmata in accordance with benignity and malignity was that such a grouping suggested the idea of a sharp line dividing malignant from benign neoplasmata, which was far from being true. There was a gradual ascent from benign to malign neoplasmata. A benign tumor might surely cause death, not because of its nature, but because of location. Furthermore, malignity had come too commonly to signify cancer. Such a classification was very unscientific.

Dr. Charles B. Nancrede, of Philadelphia, also discussed the question,

WHAT ARE THE OBJECTIONS TO THE GROUPING OF NEOPLASMATA IN ACCORDANCE WITH BENIGNITY AND MALIGNITY?

and then that of

WHAT CONSTITUTES MALIGNITY, HISTOLOGICALLY AND CLINICALLY?

One form of histological element did invade the histological elements of a different type until we came to malignant tumors, and malignity, briefly expressed, was invasion of one form of histological elements by histological elements of different types, the invading elements being unable to develop into a stable tissue.

He further discussed Question 6, "What is the mechanism of the necrotic process which so often occurs in certain neoplasms?"

It was due to insufficient blood-supply to the histological elements. Cicatricial tissue might be the direct cause of the anæmia in the histological elements.

Dr. Nancrede further discussed Question 13,

ARE MALIGNANT NEOPLASMATA EVER CURED?

and expressed his views in the affirmative, and gave as illustrations cases of removal of cancer from the lip. When, as in cases referred to by Dr. Gouley, the disease remained absent many years after removal, and then again occurred, he thought here it could not properly be regarded a recurrence any more than a second attack of scarlet fever could be spoken of as a recurrence. The evidence was that the disease was local in the beginning, and if so, there was no reason why it might not be cured by removal.

Dr. Nathan Jacobson discussed, at length, Questions 5, 6, and 12. He thought cancer could be cured by early and thorough excision. A second attack after some years did not mean recurrence.

Dr. W. H. Carmalt, of Connecticut, thought the development of malignant growths simply due to failure of cellular tissue, whether connective tissue or epithelial, to arrive at maturity, and in this immature state developed afterward in an indefinite way. Malignant tumors should be divided into those of connective tissue and epithelial type, a much better classification than into sarcoma and carcinoma. Sarcoma usually invaded distant organs through blood-vessels, carcinoma through the lymphatics. He had known removal of malignant tumors not to be followed by recurrence for years. He favored radical removal.

Dr. Joseph D. Bryant discussed in a paper Questions 7, 8, and 13.

The reason for occurrence of malignant tumors in parts distant from the primary seat was as much a mystery as was that of normal vital force. Facts pointed at present as follows: (1) That sarcoma and carcinoma were dependent entirely on local causes for their existence in many cases; (2) that they were a local manifestation of an inherent peculiarity of certain tissues; (3) that they started in local irritation. The local manifestations were first to be seen and first appealed to the fears of the patient. How did malignant growths invade neighboring parts? There seemed to be no doubt now that it was by cell-nuclei, or cell-passage from the primary point through lymphatics or capillaries and vessels. Clinically and theoretically the rapidity of the growth corresponded to its vascularity, richness of neighboring lymphatics, softness of surrounding tissues. Malignant disease, as such, was not inherited, but he thought a vulnerability of tissue favoring its development might exist in the offspring. Could malignant neoplasmata be cured? The question could be safely answered in the affirmative. The site of the growth and early removal had much to do with cure. The knife was the instrument with which to operate.

Dr. Charles W. Brown gave his personal experience with removal of cancer in prolonging life.

Dr. E. M. Moore continued the discussion on tumors, giving personal experience with malignant neoplasmata. Some years ago, when the microscope came into use, it was thought the questions of the pathology and diagnosis of cancer would be definitely determined. But to-day as much reliance could be placed upon clinical experience independent of the microscope. He had hoped to hear during this discussion that some German had discovered a microbe to which the disease could be positively attributed. But here again he had been disappointed. Dr. Moore had removed a number of cancerous breasts, the patients living years afterward without a recurrence, and death resulting from some other disease. The older the patient, the less likely was there to be a return. While he had regarded cases operated upon many years before, in which there had been no recurrence, as cured, yet he recalled the case of a man who came to have a cancer of the lip removed, and stated that at the same place a cancer had been removed seventeen years before, there being recurrence only after sixteen years.

Dr. Cronyn, President, said, regarding heredity, that he had seen the disease in four generations of one family, affecting in one generation two brothers, in another three brothers; in one case the cancer appeared in the side neck, and in the same place in the patient's son.

Dr. Nancrede mentioned some cases in Philadelphia in which there had been frequent removals, the patients' lives undoubtedly being prolonged and made more comfortable. He could not easily understand how one could transmit to offspring a disease which did not appear in the parent before sixty. Sir James Paget had explained that by heredity it was not meant the disease was transmitted absolutely, but potentially. He was unable to understand that explanation, but he could understand an inherited tendency to premature senility in some particular tissues of the body, and disease attacking such tissue was more likely to be malignant than if it attacked relatively younger tissue.

Dr. Wood recalled a remark of the late Dr. Alonzo Clark, that if a mother had cancer and had daughters, one or more of them would be likely to develop cancer. Dr. Wood recalled one instance in which two daughters developed cancer, the mother having had cancer of the uterus. He thought there might be a predisposition to the disease, just as there might be to phthisis.

Dr. C. L. Squire gave the history of a woman on whom eight operations for cancer, commencing in the breast, had been done within five years, the entire period covered by the disease being fourteen years. Three years had elapsed since the last operation, and still no return.

Dr. Gouley still held to the view that in the cases narrated, in which freedom from cancer continued many years after operation, that the second attack was properly designated a recurrence. The essential of cancer was polymorphism of the cells. Cancer was of pan-blastic, sarcoma of meso-blastic, origin. The name should be determined by the elements of which the tumor was chiefly composed. The microbic and leucomaine theories were still under study. He thought there was no doubt of spread of sarcoma chiefly through the blood-vessels, and of cancer through the lymphatics. Regarding hereditary predisposition, Broca had published the records of a number of cases of the disease existing in three or four generations. He then gave a scheme of classification and nomenclature of neoplasmata. He claimed it was shorter and simpler than others; it was not introducing new names; they were very descriptive.

Dr. Moore had listened to Dr. Gouley's statement that both sarcoma and cancer, or epithelioma, were composed of the same cell-elements; the difficulty in distinguishing the one from the other, where the number of cells were pretty equally divided, still remained. The classification sounded well, but he feared physicians would not stand the long names.

Thursday, October 11th—Third Day, Morning Session.

ELECTION OF OFFICERS.

William T. Lusk, M.D., of New York, was elected President for the ensuing year.

Vice-presidents by Districts: First, Dr. S. H. French; Second, Dr. R. C. McEwen; Third, Dr. Elias Lester; Fourth, Dr. Thomas R. Strong.

Members of Council by Districts: First, Dr. Douglas Ayres; Second, Dr. J. B. Harvie; Third, Dr. T. H. Chittenden; Fourth, Dr. R. T. Menzie; Fifth, Dr. A. L. Carroll; and Dr. William B. Eager.

ADDRESS IN MEDICINE.

Dr. John Shrady chose for his subject

MEDICAL NEW YORK IN 1800.

He sketched the social and political aspects of the times. He gave items of many local changes and condensed biographies of many medical celebrities, among them, David Hosack, Samuel L. Mitchill, and Wright Post. He maintained that the condition of the profession at that time, considering the general surroundings, was as good as that of the present day; that there was the same panting after knowledge, the same struggles, the same self-sacrifice, the same ingenuity of resource, and the same devoted humanity. They constituted no mean connecting links between the past and the present, and deserved well of posterity, for it is to be considered that their surgery was without anæsthesia, and their medicine without the instruments of precision.

Dr. Isaac E. Taylor read a paper on

INVERSION OF THE UTERUS AFTER SOMATIC DEATH.

It was true that there were only rare cases in which the child was expelled and the uterus inverted after the death of the mother, but the subject deserved attention because of its importance. To the mechanism of the inversion he would call attention. Three important reasons, or theories, had been advanced in explanation of posthumous delivery of the child and inversion of the uterus: 1, Spasm of the uterus or rigor mortis; 2, decomposition of the tissues and fluids in the abdomen, and the evolution of gases; 3, contraction of the uterus, consequent on the irritability of the muscular structure of the uterus which ensued after death. Physiology had shown that muscles did not lose their irritability immediately or very soon after death of the general system, but it did not explain why the muscles of the uterus, powerless at death, should afterward with remarkable energy force the expulsion of the child, much less turn the uterus wrong side out. The uterus after birth of the child and expulsion of the placenta had been found as firmly contracted in these cases as after labor in the living mother. The uterus was one of the last organs to undergo decomposition. The contraction of the womb after death was not due to the influence of the nerves, as these were dead. After offering objections to other theories, which would mostly suggest themselves to every mind, Dr. Taylor said he would suggest the belief that the investigation of the mechanism of posthumous delivery of the child, and inversion of the uterus after death, would confirm his opinion of the mechanism of normal labor expressed in 1863, and show that the same explanation applied here, namely, that inversion was effected by one continuous persistent contraction of the uterus, and the inversion was from below upward, instead of from above downward.

Dr. C. A. Leale said the subject was one of great importance from a medico-legal point of view; the physician was called, and found the mother dead and a child born, perhaps dead, perhaps alive. According to the law in some States, if the mother was dead when the living child was born, and then afterward died, the heir would be the husband of the mother; but if the child was born dead or died before the mother, the property went to the mother's heirs.

ADDRESS ON OBSTETRICS.

Dr George T. Harrison, in his address, reviewed recent progress in obstetrics. An epoch-making procedure was introduced with freezing the body before making dissection. It had been established that in the parturient, as in the unimpregnated state, there was a lower segment of the uterine body, distinguished from the neck. In parturition there was an upper active and a lower passive part, although the functional did not correspond to the anatomical division between the body and cervix. The body contracted actively during delivery, the lower portion remained passive. The "ring of contraction" corresponded to the lower boundary of firm attachment of the peritoneum. Hoffmeyer had confirmed statements made by Dr. Taylor in 1865 that the cervix remained in its integrity to the end of pregnancy.

There had been some reaction from Crede's method of expulsion of the placenta, but he could not concur entirely with the views of Schroeder. Crede's method should be reserved for cases in which the placenta did not become detached, or those in which it remained fixed in the cavity, its expulsion being prevented, perhaps, by a narrow line of contraction in the neck.

Much valuable literature had recently appeared on the yet unsettled questions of eclampsia. There had been progress in study of the physiology of the fœtus, particularly by Prior. It had been shown that substances could pass from the circulation of the mother to that of the fœtus. Progress, in recent years, had, as was well known, been made in antiseptics, particularly since the discovery or acceptance of the fact of transmissibility of infectious disease.

What more important procedure could be mentioned than the improved method of Sänger for Cæsarean section?

Dr. Thomas H. Manley then read a paper on

TRAUMATIC GANGRENE,

in which he first cited his experience with five cases, containing the following salient points respectively: In the first, the swift and appalling virulence, and almost immediate lethal action, of the bite of a rattlesnake, the bite being in the arm of a man, and death following in about nine hours; the second, though collateral circulation was established after the brachial artery was torn across, mortification quickly supervened on injury to the arm, and was as promptly arrested by cutting off the affected tissues; the third illustrated how serious a condition might arise from a trifling injury, which was the crushing of the big toe, afterward threatening gangrene, when it was removed; the fourth, that the surgeon should use every effort to save every inch of tissue which still showed a spark of life; the fifth, the case of a child, aged seven, run over by a horse-car, crushing a leg, the failure to save life, because of operating too early after the injury, and development of gangrene, instead of waiting for the vital forces to rally.

Regarding preventive treatment, the modern enthusiast, he said, might believe that if antiseptics were rigorously applied inflammation would be impossible. If we unconditionally subscribed to that doctrine it would be idle to discuss other measures.

If inflammation would develop in spite of efforts to control it, we could often lessen its violence by free bloodletting in the vicinity of the swollen parts.

When was interference with the knife justifiable? Shall we operate in spreading gangrene? He answered in the affirmative; he would not wait for the line of demarcation, but one should be positive of mortification before amputating. He would rather include in the incision some of the tainted part than go too far up, especially if it necessitated the involvement of a joint.

(To be continued.)

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, October 4, 1888.

ABRAHAM JACOBI, M.D., PRESIDENT, IN THE CHAIR.

REPORT OF R. C. M. PAGE, M.D., DELEGATE FROM THE NEW YORK ACADEMY OF MEDICINE TO THE CONGRESS RECENTLY HELD IN PARIS FOR THE STUDY OF TUBERCULOSIS IN MAN AND ANIMALS.

DR. PAGE stated that he had made the following brief summary of conclusions from the transactions of the Congress for the Study of Tuberculosis, recently held in Paris, more as memoranda for his own reference than as a report for the Academy of Medicine, as he had not expected to be called on for one. It had been submitted to Drs. Villemin and Landouzy, however, and received their verbal approval, whatever mistakes found in it being his own:

1. True tubercle generally (not always) contains the bacillus first supposed to exist by Bouchard, of Paris, in 1880, but afterward discovered by Koch, of Berlin, in 1882. All other substances—products of inflammation in connection with other conditions than tubercle (caseous, for example), and occurring in non-tuberculous subjects—do *not* contain Koch's tubercle bacillus. That is the true difference between them. When true tubercle does not contain the bacillus, it is because the latter has been liberated and escaped, owing to breaking down of tissue by pathological process, or else the tubercle yet contains only germs of undeveloped bacilli. True tuberculous virus, therefore, though it may not contain Koch's bacillus, is, nevertheless, capable of reproducing itself by inoculation under certain conditions, by reason of bacillary germs. Any other substance than tubercle that contains Koch's bacillus, or its germs (caseous products, for example, which have become infected by the bacillus or its germs, as may occur in tuberculous subjects), can also produce true tuberculosis by inoculation. Other substances, however, apart from tuberculous subjects and *not* containing Koch's bacillus or its germs, *cannot* directly produce true tuberculosis. Koch's bacillus thrives best at a temperature of 98° to 100° F., and is susceptible of proliferation between 86° and 104° F., although it may live beyond these extremes. It attacks the lungs by preference, although no tissue is exempt from it, and it may remain virulent in running water at a temperature of 60° F. for six weeks, and in stagnant water for eighteen weeks; in dried sputa for a month.

2. Koch's bacillus is the *cause*, not the result, of tuberculosis (inherited or acquired), however this fact may be yet doubted or disputed by some. In case of inheritance, the disease may be directly transmitted to the ovule by spermatozoa infected with bacillary germs.

3. Tuberculosis is a contagious disease under certain conditions, especially those that tend to produce lowered vitality, and is transmissible between man and animals by the digestive tract, as proved by the experiments of Chauveau, in 1868, through uncooked tuberculous drink and meat, especially cow's milk and beef. Also, by the respiratory tract, through infected air, as proved by Villemin, in 1869, and Tappeiner, in 1876–77. Hence the necessity for sanitary measures as a means of prophylaxis, especially with reference to thoroughly cooking meat and boiling milk, even though previously inspected. True tuberculous virus is also transmissible by inoculation, by subcutaneous injection, or through the integument stripped of its epidermis, as proved by Villemin, in 1869; and, also, perhaps in the following ways: By other mucous membranes than those already mentioned, as the conjunctival and genito-urinary; by dermatoses which destroy the epidermis; through the sudoriparous and sebaceous glands; and, finally, through wounded and absorbing surfaces.

4. In the early diagnosis of doubtful or suspected cases of pulmonary tuberculosis in man, if physical signs are insufficient, Koch's bacillus should be sought for in the sputa by an expert; but it is not always possible to find it at first, because the bacillus may not have yet been liberated, or only its germs may exist. To verify it, two or three lower animals (rabbits. for instance), may be kept under the necessary devitalizing conditions, inoculated with the suspected sputa, and killed at varying intervals after a month or more. If it is the disease in question, some tubercles containing Koch's bacillus will usually be found in the different organs.

5. No practical means for destroying Koch's bacillus in patients has yet been discovered, although antiseptic inhalations and injections have been employed by some, and even localized surgical treatment, as the drainage of cavities, in certain advanced cases.

6. That the management of tuberculosis in man at the present time should therefore be directed toward two objects chiefly: (1) Prophylaxis by proper attention to climate, food, exercise, and the like; and (2) treatment by means of medicines only as symptoms arise that require it.

THE REPORT OF A DELEGATE TO THE BRITISH MEDICAL ASSOCIATION

was read, referring briefly to some of the work done at the meeting.

DR. E. G. JANEWAY then read a paper, entitled

REMARKS ON THE DIAGNOSIS OF DISEASES OF THE LIVER AND THE FEVER ACCOMPANYING BILIARY OBSTRUCTION.

His object was to present certain facts, and groupings of facts, showing some of the difficulties attending diagnosis of diseases of the liver which had come under his observation, and said he had not attempted to make a complete paper on the subject. He first spoke of the difficulty of recognizing diseases of the liver as compared with affections of the heart, lungs, and kidneys, the physical signs in the case of the heart and lungs being more definite, while in the case of the kidneys the urinary examinations gave a clue. The physical examination alone would never prove sufficient in the majority of diseases of the liver; we had to conjoin with it a study of the etiology and symptomatology, and in many cases had to take into consideration the condition of the spleen. He then took up certain circumstances which would be likely to lead to a misinterpretation of the size of the liver. This was well illustrated by the uncertainty in diagnosticating perforation of the bowel based on loss of liver flatness, which some mistakenly regarded as an absolute sign of intestinal perforation. He had known the sign to fail both where there was a portion of intestine between the liver and diaphragm, and where the liver was turned up by a tumid condition of the abdomen, and where the liver was adherent to the diaphragm from perihepatitis. Thus in one case there would be loss of liver flatness, while in the other it would be present. We also met with difficulty in studying diseases of the liver itself. Many conditions of the heart, lungs, abdominal viscera, particularly enlarged conditions of the kidney, were likely to deceive the diagnostician by making the liver sometimes appear too small and sometimes too large. The author alluded to cases which he had seen, where tumors behind the liver had pushed it forward, making it appear larger than normal, as aneurism, and to some cases of enlarged right kidney simulating enlarged liver. In one the kidney was enlarged in a manner that the liver came down over it, and in the other the kidney had grown upward, pushing the liver obliquely, so that the left lobe was over the kidney. Again, a tumor of the intestine or omentum sometimes became adherent to the liver, simulating hepatic enlargement. Fecal impaction had rarely been a source of trouble to him in making diagnosis, although it was frequently mentioned in the books.

Difficulties also attended the diagnosis of diseases of the liver based on the size of the organ. The same kind of liver might be either large or of medium size. Nodulation of the liver was an important aid in diagnosis, but even that sign was not always reliable, for sometimes the organ was large and smooth, owing to the distribution of the disease which usually caused nodulation—cancer and cirrhosis. One division of cases was into smooth, large livers, and nodular large livers, but if one placed entire reliance on the physical signs he would here also be likely to err.

Turning his attention to small livers, it was often difficult to say whether the organ was somewhat diminished in size, and even when there was much diminution it was still necessary to consider the different conditions which might be the cause.

In jaundice we had not a great, but a certain, amount of help in diagnosis. When the diseased process surrounded the bile-ducts it was more likely to give rise to jaundice; a small process might cause it, while one of very considerable size might not, it being a question of the site of the process. He spoke particularly of the infrequency of jaundice in solitary abscess of the liver, compared with cases of multiple abscess. He cited a case of acute yellow atrophy, with no obstruction of the duct, in which there was complete absence of bile from the stool, showing that obstruction of the duct was not necessary to cause complete absence of bile from the fæces.

He then passed to the question of fever and jaundice. Sometimes in cancer of the liver there was fever; it was not absolutely necessary that there be an inflammatory process in order to have fever. Again, it should be borne in mind that fever might be due to an intercurrent process, and not to the condition of the liver. He spoke of the little fever sometimes present in abscess, and of the combination of fever and jaundice in difficult diagnosis, and referred to Charcot's intermittent hepatic fever, which occurred in connection with obstruction of the bile-ducts and simulated malarial fever. Weil's disease was apt to deceive the physician, the nature of this affection not being as yet thoroughly established.

The author had performed exploratory puncture many times, and had had no injury result. Abscess might be present, however, and fail to be detected by puncture. It was best to introduce the aspirator in one or two places in doubtful cases, choosing the axillary space or the posterior part of the chest, and reaching the deeper part of the right lobe. He also spoke of the value of perihepatic friction and fremitus as aids in establishing the condition which produced inflammation on the surface of the liver; that it was of particular service in hepatic abscess, as showing the point at which puncture should be made. The quantity of urea passed was an unreliable diagnostic element so far as it related to the liver.

Dr. Beverley Robinson said, with regard to deep abscess of the liver, that its diagnosis was likely to remain obscure unless several deep punctures on successive occasions were made. He had not known puncture to result injuriously.

The President inquired whether abscess of the liver was frequently present without fever.

Dr. A. L. Loomis would say, from personal experience, that fever was always present in multiple abscess; but in single abscess, abscess without known cause, fever was often absent. He had entered too late to hear enough of the paper to enable him to discuss it.

The President said, with regard to the liver seeming to be enlarged when it was not, that there were a number of reasons for this. For instance, the question of whether the liver and spleen were enlarged in rachitic children had often been discussed, some holding to the affirmative and some to the negative. Great mistakes could be made in judging of real enlargement, for in the fœtus the liver was very large and it remained so a number of years, whereas this great size might be mistaken as abnormal. Then in rachitic children the arteries were large, compared with the heart, and large arteries meant low blood-pressure, and this meant temporary or permanent large liver from mechanical stasis. Then the deformity of the chest in rachitic subjects was likely to throw the liver downward and make it appear larger than normal. Inflation of the intestinal tract might change the position of the liver, causing it to appear smaller than it really was, while pressure from behind might make it appear larger than its actual size. Then rarely dislocation of the liver misled to a diagnosis of enlargement. He asked Dr. Janeway what influence hemorrhage had on the size of the cirrhotic liver, and the influence it was likely to have on diagnosis.

Dr. Janeway replied that he thought hemorrhage might occur at different periods of cirrhosis, both when the liver was large, when of moderate size, and when small. In hospital practice patients often entered and died with some other affection, and at autopsy cirrhosis of a liver of about normal size be found, although disease of this organ had not been recognized during life for want of a previous history. In private practice, on the other hand, a diagnosis lacked confirmation frequently because an autopsy could not be obtained. Thus the answer to the President's question was, that there were not a few cases of hemorrhage from the liver of moderate size or a little enlarged, the hemorrhage perhaps being repeated, and the patient dying before the liver shrunk. The hemorrhage would have more effect perhaps on the spleen than on the liver.

The President recalled a case of repeated hæmatemesis in large amount, extending over six or seven months, but in spite of this the patient had a small liver and a very large spleen.

Dr. Van Santvoord recalled a case of hemorrhages at long intervals, very much enlarged spleen, and no appreciable change in the liver—the diagnosis of cirrhosis of the liver proved correct.

Dr. Loomis, after being informed more particularly of the nature of the discussion, said one was likely to make great mistakes if he depended on physical examination alone in diagnosticating diseases of the liver. One had to rely much upon the subjective symptoms. Exploration for abscess not infrequently failed, although abscess was present. He had seen in the early stage of cirrhosis of the liver, when the organ was considerably enlarged, diminution in the size of the organ follow in a short time hæmatemesis. The hemorrhage seemed to have relieved the hyperæmia present in the early stage of the disease. In reply to the President's question, how numerous were cases of abscess of the left lobe compared with abscess of the right, Dr. Loomis said he had rarely seen single abscess in the left lobe.

Dr. Janeway, answering the same question, would say between a third and a fourth of single abscesses occurred in the left lobe.

The President's experience in this respect corresponded with Dr. Loomis'.

Dangers of Saccharin.—M. Worms read a paper at the Académie de Médecine, in which he stated that he administered saccharin, in varied forms, to four persons suffering from diabetes. One, after a course of two months, still suffered no inconvenience therefrom; but the other three, at the end of a fortnight, complained of loss of appetite, indigestion, and weight in the stomach, which symptoms continued for eight days after leaving off the saccharin. The doses were resumed in the case of one of the patients, and a return of the symptoms complained of took place at the end of ten days. This proved that it was dangerous to put saccharin into the food of anyone suffering from diabetes; and, moreover, that as it was an indigestible substance, the general employment of it might result in serious consequences to the public health. This fact is at present worth knowing, as it is proposed to substitute saccharin for cane-sugar in many ways, such as in sweetening acid wines, and in the manufacture of syrups, it being half the price, and its power of sweetening so much greater than that of sugar. —*British Medical Journal*.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Eleventh Annual Meeting, held at St. Louis, Mo., September 25, 26, *and* 27, 1888.

(Special report for The Medical Record.)

The meeting was held in that beautiful building, the Pickwick Theatre, situated in the residence portion of the city. It was opened by prayer, after which Mayor Francis, of St. Louis, made an

ADDRESS OF WELCOME.

The mayor, who is seeking advancement in the political scale, was out looking for his political fences in a distant part of the State and showed his appreciation of doctors by riding all night to be present and bid them welcome, "with genuine Western hospitality, to St. Louis, the commercial metropolis of the Mississippi Valley, the garden spot of the earth over which the star of empire paused in its westward course." The mayor's speech was heartily applauded and he doubtless made some votes to reward him for his long ride, for his speech was not without political reference.

The Chairman of the Committee of Arrangements, Dr. I. N. Love, then introduced in a neat speech the venerable and beloved Dr. L. C. Boislinere, who welcomed the Association on behalf of the medical profession of St. Louis. He dwelt on the magnitude of the Mississippi Valley, which was as large as Europe and contained one-half of the inhabitants of the country. He referred to the brightest stars of this firmament, Cincinnati, Chicago, New Orleans, and St. Louis. Horace Greeley said, "Young man, go West," and they have come West, where we make presidents and governors of them. Gross, Emmett, Sims, Parvin, and Bartholow were Western men. We make great men in the medical profession here, and in the future we mean to keep them. It will not be long till our hospitals, colleges, and universities will be as great and attractive as those in the East.

THE PRESIDENT'S ADDRESS

was delivered by Dr. Dudley S. Reynolds, of Louisville, Ky. This gentleman, after being happily introduced by Dr. Love, made a few remarks. He said we were here for the discussion of grave questions which make up the branches of the profession of medicine. He quoted from the mayor's address, in which he referred to the influence of the medical profession on legislation, and said that this influence was not anything near what it should be (applause). There is now stalking abroad, in the Southern portion of our country, a pestilence which we think might have been avoided had we been hearkened to in the halls of legislation. He thought the subject of presidents' addresses was a well-worn one and knew of no subject on which he could interest them, and after thanking the Association for the honor conferred on him resumed his seat.

Dr. J. M. Matthews, of Louisville, replied to the words of welcome on behalf of the visiting members.

The reading of the minutes was dispensed with, after which the committees and officers made their report.

Dr. C. G. Comegys, of Cincinnati, read the first paper, on

YELLOW FEVER.

He considered first what the profession could do to assuage this terrible disease and prevent its spread to other cities. The phases observed in those stricken with the disease were related, and the clinical history given. We know that yellow fever depends on a specific poison but what that poison is we have not discovered as yet. He thought the fatal results in this disease were due to a very intense degree of the "Brightoid condition." He recommended a hot bath to insure free diaphoresis, and repeated to relieve the kidneys. Where a hot bath could not be given he did not object to the use of a spirit lamp or steam with the patient covered by blankets. Boiled ears of corn make an excellent substitute in country practice. Cool lemonade, potash salts, nitro-glycerine are excellent remedies, the latter when there is cardiac dropsy. Alcoholic stimulants he considered very baneful unless the kidneys were freely open, as they are quite impervious to alcohol unless open. Alcohol under these circumstances acts as an irritant. He then reviewed the subject of protection by vaccination and expressed the hope and the belief that the future was more hopeful in this direction.

Dr. William Bailey, of Louisville, said that if he took any exceptions at all to the most excellent address, it would be that at certain times we have no more certain agent for elimination than alcohol. He believed that the Southern portion of this country was more afflicted by quarantine than by yellow fever.

A SHOT-GUN QUARANTINE IS HORRIBLE.

Does it do any good? Certainly not, unless it is complete, and completeness is about impossible. The Government should quarantine against its introduction into the country, but sections of our land should not quarantine against other sections. In 1878 great numbers of refugees, 10,000, came to Louisville. They filled the hotels, crowded the boarding-houses and private residences with themselves and their luggage. We did not believe that it would spread, then. We had a yellow fever hospital, and in it were about thirty resident physicians and nurses, day and night busily engaged with the sick. The disease was carefully studied, post mortems and microscopic examinations were made with great frequency. Fifty others were in daily attendance, including every minister in the city and every charitably disposed woman, and from the one hundred and fifty cases none took the disease. So much for personal contact. Previous to this we had thought the disease not indigenous to our climate. Within two squares of the spot where the luggage was emptied out and the cars cleaned, we had thirty or forty cases, none having had personal contact with any sick, but with the luggage and clothing. We again invite yellow-fever refugees as we did then, but we ask them to leave their luggage at home. Louisville would rather clothe them than have them bring their dangerous clothing with them. In inviting them we believe we will save more lives than we will lose. There may be some reason for such cities as Memphis for surrounding themselves with a cordon, for she has suffered terribly, but can we not take the risk for suffering humanity?

Dr. McPheeters, of St. Louis, wished to speak of State and city quarantine. He indorsed Dr. Bailey thoroughly. Previous to the war he was for a time surgeon to the United States Marine Hospital here. Many patients having the yellow fever came here and were placed in the fever wards with other patients. Not much attention was given to them, they created no panic, and, so far as he was able to learn, no case originated from these. He believed that the whole country suffers more on account of quarantine than the yellow fever. The brutality of shutting our doors against the refugees is worse than the yellow fever. Louisville's action is creditable to her.

Dr. Homans, of St. Louis, Mo., Secretary of the Missouri State Board of Health, moved that a committee of five be appointed to consider this subject of yellow fever, and report at a later session of this meeting. This motion was adopted.

Dr. Comegys, in closing the discussion, said that he certainly agreed with the gentlemen who had taken part in the discussion on the question of the non-contagiousness of the persons or patients suffering with the disease. A man without clothes might go anywhere and not spread the disease. He insisted further on the necessity of hot baths.

INFANT FEEDING

was the subject opened for discussion by Dr. J. A. Larrabee, of Louisville. He discussed the virtues, real and imaginary, of the various foods for babies. Condensed milk he thought a convenient and good substitute for mother's milk. We accept the theory of fermentation, and we know there is no such thing possible without the microbe, which gets into the milk after it leaves the cow. This thing of summer complaint has to go to the wall. All the harm done by teething and the second summer is now out of the question. The reason of more sickness occurring during the second summer is, that during the first summer the food is taken directly into the child's mouth from the mother's breast hermetically sealed. In the second summer the child gets a greater variety of food and microbes. Then, too, artificially fed children are generally overfed children. It is difficult for the mother, for the nurse, or even for the doctor to tell the difference between the cry of colic, the cry of an overdistended stomach, and the cry of hunger. The child often wants not food, it wants water. In the cities it generally gets both together. The bottle makes too convenient a stopper for the crying child, be it from hunger, colic, or over distention. A very good thing to add is a little salt, now and then.

Dr. Dudley S. Reynolds, the President, stated that Mr. Ernest Hart, the editor of the *British Medical Journal*, and his wife had been instrumental in founding a charitable society in London for the purpose of teaching dairymen and nurses how to keep and prepare milk.

Dr. Cook, of Vandalia, Ill., thought sterilization of cow's milk to be one of the most important things, also the selection of a healthy cow.

Dr. Mayfield, of St. Louis, sterilizes his milk. He filters his water through charcoal and sand, and pumps it into a tank without it having access to the air and heats to two hundred and twelve degrees. He then mixes the milk with this water half and half, and sweetens with a little sugar. He thinks we should insist on the mother nursing her child and not allow her to avoid this duty.

Dr. Nicholas Guhmann, of St. Louis, thought that the simpler you treat children the better for them. They should not be given much medicine.

Dr. Middlekamp, of St. Louis, thought that in addition it would be well for us to secure a wet nurse. He had employed the method of J. Lewis Smith, extract of pancreatine and soda in milk, described in "Pepper's System of Medicine," vol. ii.

Dr. William Bailey, of Louisville, thought it might do the child harm by removing from it the necessity of digestion. If the child can digest we should not digest its food for it.

Dr. Larrabee said that he was directly and totally opposed to the medication of infants. He could not see the need of antiseptics where there was no sepsis. He certainly agreed with what had been said in reference to digestion. The ferments are microbes. The pancreatine has a very putrescent odor. Feeding barley-water previous to nursing has cured completely many cases of screaming gastralgia in infants.

The granddaughter of Ephraim McDowell, Mrs. Mary Ridenbaugh, being present in the room the attention of the Association was called to that fact and she was greeted on the part of the Association.

DISEASES OF THE MIDDLE EAR

was the subject of an essay by **Dr. C. H. Beard**, of Chicago. The literature of otology is very limited, proving the status to be low. The surgery of suppuration of the middle ear, he thinks, will soon take a leap forward. He hoped to inaugurate an era of greater energy and investigation in the field of otology. Otology stands to-day with bowed head before the membrana tympani. It was his humble opinion that there are no cases of chronic suppurative inflammation of the middle ear that will not yield to persistent cleansing with aseptic warm water, and as thoroughly drying the same. He exhibited instruments for cleansing the middle ear through the Eustachian tubes. The naso-pharyx, he thought, was a part which was much neglected.

Dr. William Dickinson, of St. Louis, thought diseases of the ear were not trivial in their character, and merited careful attention. He recited cases of proof.

Dr. Thompson, of Indianapolis, thought that the time to look after this matter was in infancy, when catarrhs commence and increase with every cold that is taken.

The President expressed his belief that chronic suppuration of the middle ear was sufficient ground to refuse an applicant for life assurance, and cited a case proving this fact.

Dr. Beard replied to the remarks of the other gentlemen.

RETINITIS ALBUMINURICA

was the subject of a paper by **Dr. William Dickinson**, of St. Louis. He reported a number of cases, and thought the symptom one of extreme gravity. We should never regard any disease of the eye as unimportant.

Dr. William Bailey, of Louisville, asked that Bright's disease be widened a little, and not be confined to the kidney. Retinitis albuminurica he thought only a part of the general disease. "I believe that in these cases in pregnancy we can act by elimination and save the mother, her vision, and her child."

Dr. Dickinson replied.

EXOPHTHALMIC GOITRE

was the subject of a paper by **Dr. R. Bower**, of Chicago. In this paper he lauded greatly strophanthus as a remedy, but would not admit that he relied on it entirely, depending, to a certain extent, on hygienic treatment, which he thought very necessary.

Dr. Dickinson reported a few cases.

Dr. T. R. Prey, of St. Louis, favored the use of strophanthus.

Dr. Bower, in closing, requested of his hearers that they try strophanthus in this trouble, and also in sick headache and epilepsy, and let him know their results.

DIPHTHERIA

was the subject of an essay by **Dr. C. R. Earley**, of Ridgeway, Pa. His paper was a report of his experience for six years with this disease. He thought from the mass of literature extant this was a much studied disease. Carpets, paper, and cellars, he thought, had done much to bring it on. It was not common when these things were unknown. He thinks the disease constitutional, and that the treatment should be likewise constitutional.

A CASE OF STRANGULATED HERNIA,

in which an operation did not relieve the symptoms, and which was followed by laparotomy and case resulted fatally, was reported by **Dr. Arch Dixon**, of Henderson, Ky. No autopsy was permitted, but it was probably incarcerated at first, then became strangulated. Operation has occurred as late as eight or ten days after strangulation, with restoration of the gut.

CONSANGUINITY IN MARRIAGE

was the subject of some verbal remarks by **Dr. E. S. McKee**, of Cincinnati, who was called upon by the President, who stated that Dr. McKee had made a special study of this subject. Dr. McKee said that there was, permeating all classes, nations, and ages, a belief that consanguineous marriages were detrimental to the welfare of the offspring. He had occasion several years ago to study up this subject thoroughly, and his investigations had led him to the belief that there was nothing in it. His opinion was that the children of healthy cousins would be healthy, and those of unhealthy cousins would be unhealthy. This would occur entirely independent of the fact of consanguinity. We are often perplexed by counting relationship by two methods, the civil and the canonical. The former counts the number of generations up from one individual to the common ancestor, then down to the other. The latter counts in but one line, this the longer from the common ancestor. This law is imperfect, making persons in the same relationship to a certain person when this is not so. Prohibiting marriage in the third degree by the canon law prohibits many more than by the civil law. The Levitical code is very generally followed by the various States in this nation, but New Hampshire, Ohio, and Indiana forbid the marriage of first cousins. Most States forbid a man to marry his aunt or niece, but this is allowed in New York.

THIS QUESTION OF COUSIN-MARRIAGES

has been studied very thoroughly by Mr. George H. Darwin, of London. He found in London the cousin marriages 1.5 per cent.; English urban districts, 2 per cent.; rural districts, 2.25 per cent.; landed gentry, 3.5 per cent.; aristocracy, 4.5 per cent. The average in England is 3 per cent. while in Scotland it is 5.25 per cent. A thorough search through the institutions of the insane, deaf and dumb, and idiots, revealed to Mr. Darwin that between 3 and 4 per cent. of the inmates were the descendants of consanguineous marriages. In fact, all reliable statistics go to show that about the same proportion of deaf-mutes, idiots, and insane persons, are descendants of consanguineous marriages to the whole number of these unfortunates as the number of consanguineous marriages is to the whole number of marriages. Consanguineous marriages appear to be aristocratic. Physical and mental weakness, frequently found in the higher classes, has been laid at the door of consanguinity in marriage. Is it not much more probably due to debauchery, extravagance, and corruption?

STERILITY,

among the many other defects, has been laid at the door of consanguinity. We find, on carefully analyzing large numbers of cases, that the fertility is slightly greater in marriages of consanguinity than in the non-consanguineous. This probably occurs from the fact that cousin marriages are much more liable to occur where there are large families of cousins together. In these cases the fertility is hereditary.

The marriages of Brown and Brown, Smith and Smith, Jones and Jones, is probably the marriage of distant relatives though they themselves are unaware of the fact. Then, too, all men are the sons of their mothers, but not all men are sons of their fathers, so to speak. Might not this illicit intercourse result in the marriage of relatives supposed to be non-relatives, thus vitiating statistics? The evil results following consanguinity are probably *post hoc*, not *propter hoc*. They may be due to one of a thousand influences. Atavism may explain many of the cases where evil results seem to follow consanguineous marriages. Evil results prove that something was wrong, but that it was consanguinity is not proven. Given a malformation or disease firmly established we have a tendency to breed true. The Quakers are educated to abhor color. Those who admire it separate themselves from the sect, and thus intensify the tendency in the remainder. The defect is also strong among the Jews, where it has probably accidentally gained a foothold and has been intensified by intermarriage.

Anatomically, physiologically, and sexually,

MAN IS AN ANIMAL.

He is subject to the same laws of propagation. In-and-in breeding is done by cunning breeders to improve the stock and put money into their pockets. The Jersey cattle have been bred for the past one hundred and fifty years on a small island six by eleven miles. We would not raise them for beef and oxen, yet they command a high price for their milk and butter. This was probably the recommendation of the first cattle on the island, and this quality has improved from time to time through in-and-in breeding. The ludicrous is approached when we enumerate the half a hundred abnormalities, among others whooping cough, which are ascribed to consanguineous marriages. We find certain factors leading to consanguineous marriages, viz.: Portions of country geographically isolated by mountains, or seas, rendering communication with the outside world difficult; religious or political sects of an exclusive nature, and aristocratic ideas of position and wealth. As examples, note the percentage in Scotland, Martha's Vineyard, the Commune of Batz, and among the Jews and Quakers. The facts deduced, by a careful study of the subject, do not warrant us in supposing that there is a specific degenerative effect caused *ipso facto* by consanguinity. Would it be better for the offspring were consanguineous marriages under medical supervision? Certainly no better than for all marriages to be under like supervision. We are warranted in concluding that consanguineous marriages, no other objection being present, should not be opposed on physiological grounds.

SOME OBSCURE AFFECTIONS OF THE RECTUM

was the subject of a paper by **Dr. J. M. Matthews**, of Louisville. He thought the term hysterical rectum not a good one. He has under his care a girl whom he has treated for three years for a chronic diarrhœa. She has six or eight evacuations daily. Every evacuation brings on a stool, and she is in constant misery. He reported the case of a well-known Kentucky physician who, every time, had a most annoying case of spasm of the sphincter, which was cured by dilatation. An Indiana doctor, at the American Medical Association at Cincinnati, consulted him for a similar trouble. These cases are relieved by local treatment; hence the trouble, he thought, was local, not secondary or hysterical, as is said to be the case by Goodell. The speaker was of the opinion that the symptoms are neuralgic. The treatment of these cases naturally depends on a correct diagnosis. He thought these obscure affections of the rectum merited our careful consideration, for many lives are wrecked by neglect and falling into the hands of charlatans. Attend to the local cause, and the nervous symptoms, so-called hysteria, will take care of themselves.

Dr. G. J. Cook, of Indianapolis, was surprised that Dr. Goodell would write such a paper. It sounded like some of the old papers on gynecology. Hysteria covers up an amount of sins which is appalling. Stricture of the rectum may be brought on by disease of the ovaries, uterus, bladder. He does not believe in the term hysterical rectum. He has seen a large number of cases of disease of the rectum and has never seen one in which a local cause could not be determined.

Dr. Pitner, of Illinois, enjoyed Dr. Goodell's paper very much, but could not agree that hysteria was the sole whole cause of the trouble. He recommended the use of hot-water injections.

The paper was further discussed by Drs. Earley and Boerck.

Dr. Matthews, in closing, said that the general condition was secondary to the local trouble in the rectum, and this organ should be thoroughly investigated.

CONDITIONS WHICH PRECEDE SERIOUS LESIONS OF THE KIDNEYS

was the subject of a paper by **Dr. C. S. Bond**, of Richmond, Ind.

Chronic lesions of the kidneys, according to the best authorities annually carry off great numbers of patients.

Doctors recognize these lesions when they have reached the condition of passing albumen and casts, but not before. This is too late, as the latest authorities state that but few cases recover which are affected in this way. Flint, Bartholow, Delafield, Loomis, etc., do not examine the urine for urea and make a record of these cases for a long interval of time. The profession at large do it much less than these standard authorities. The former agree that urea is deleterious when held in the blood and also that urea is found in the blood in increased quanti ties in these cases, yet as shown by their works they do not advise these examinations.

I have been making careful examinations, for four years past, with especial reference to the quantity of urea secreted among a class of patients answering in all other respects to those of chronic Bright's disease, except that they do not pass albumen and casts. I would regard the

RETENTION OF UREA

as of much more importance than a knowledge of albumen and casts, since by the quantity of urea I could estimate the degree of disturbance in these organs or in the system at large.

Here followed the synopsis of several cases, showing examples of three classes, artificially arranged, according to the quantity of urea excreted, and whether albumen and casts were passed. From the third group of these classes the conclusion was deduced that a patient who passes constantly but ten or twelve grains of urea in twenty-four hours is in a dangerous condition, not only of some serious lesion of the kidneys, but of having retinitis, pleurisy, endocarditis, pericarditis, or inflammation of serous membranes, as well as being distressed by his present symptoms of dyspnœa, insomnia, and neuralgic pains in various parts of the body. By giving saline cathartics and nitro-glycerine this urea can be discharged, and patient will improve proportionately if kidneys have not been affected beyond a certain point.

In conclusion, doctors are in duty bound to make these examinations if these diseases are to be prevented, which is the highest duty of the practitioner. If he does not make these examinations he must not be surprised if his patients suffer from supposed general debility, dyspepsia, uterine conditions, and finally albumen and casts be passed, and death sooner or latter follows.

Dr. J. A. Larrabee, of Louisville, thought that no more important subject could be considered than the one just discussed by Dr. Bond. The man who begins to unbutton his vest, have some stomach trouble, and must go to the oculist is in the outer circle of death from Bright's disease. In three hundred post mortems from all causes, accidents as well, made in the European hospitals, one hundred and seventy showed that they would have died of Bright's disease sooner or later.

Dr. Griffiths, of Kansas City, Mo., said that we had need of an easy method of examining and determining the amount of urea in the urine.

Drs. Gregory and **Brooks**, of St. Louis, further discussed the subject.

Dr. Bond replied that there are very simple methods of finding the amount of urea in the urine. It is only necessary to know the amount of nitrogen. There is a very simple instrument made by Parke, Davis & Co., of Detroit, which tells the amount of urea very promptly. The doctor then asked all those who had made the examination for urea, honor bright, to hold up their hands. About forty per cent. of those present held up. On motion Dr. Bond was appointed a committee with power to call to his assistance other members to investigate this subject further and report at the next meeting.

THE ELECTION OF OFFICERS

resulted as follows: President, Dr. George J. Cook, of Indianapolis; Vice-Presidents, Dr. J. D. Griffith, of Kansas City, and J. A. Larrabee, of Louisville, Ky.; Secretary, Dr. R. L. Thompson, of St. Louis; Treasurer, Dr. W. C. Chapman, of Toledo.

Committee on Credentials: Drs. C. S. Bond, of Richmond, Ind., Chairman; A. W. McAllister, of Columbia, Mo.; L. S. McMurtry, of Danville, Ky.; C. G. Comegys, of Cincinnati; D. S. Booth, of Sparta, Ill.

Judiciary Committee: Drs. J. L. Gray, Chicago; W. W. Bailey, of Louisville; C. R. Earley, of Ridgeway, Pa.

Chairman Committee of Arrangements: Dr. A. M. Owen, of Evansville, Ind. Evansville was chosen as the next place of meeting. Dr. Owen promises an interesting meeting, and he knows how to do it, for he gave an exhibition of his abilities in that line three years ago, when the Society met in that "little side-tracked city in the pocket of Indiana."

THE SOCIAL FEATURES OF THE MEETING

were marked. One evening the members were taken to Kensington Gardens by the resident physicians, where they viewed the destruction of Pompeii. The volcanic eruption and the fireworks, with several special figures for the doctors, were excellent. One evening was given up to private receptions, and three were given, one at the residence of Mr. and Mrs. R. C. Kerens at 36 Vandeverter Place; Mr. and Mrs. J. C. Drummond, 3631 Delmar Avenue, and Dr. and Mrs. N. B. Carson, 3152 Pine Street. The doctors were given a carriage-ride out to the fair grounds, and an excellent spread at the Sportsman's Lodge, where a number of toasts were responded to. They were given a special evening at the exposition and were invited to see a game of base-ball. (No one is known to have gone.)

Mrs. Mary Ridenbaugh, of Louisville,

GRANDDAUGHTER OF EPHRAIM M'DOWELL,

of Kentucky, the pioneer ovariotomist, graced the meeting with her presence.

CONTUSIONS AND LACERATIONS OF THE KIDNEYS—NEPHRECTOMY

was the subject of a paper by **Dr. H. H. Mudd**, of St. Louis. He considered contusions and lacerations of the kidney sufficient to cause hæmaturia to be of frequent occurrence, and reported cases. He thought the kidneys should be brought more into the field of surgery, the great care being not to injure the renal ganglion of nerves.

Dr. Dickinson, of St. Louis, said that nephrotomy, in his opinion, should precede the graver operation of nephrectomy.

Dr. Fairbrother, of St. Louis, thought that the trouble with these lesions was that they had very bad exit and this caused the slowness of repair.

Dr. Haley, of Kansas City, Mo., was very much interested in this subject, because it is of constant occurrence. It has generally been considered that the kidney is beyond the domain of the surgeon's help. The kidney is no more dangerous to remove than many other organs. The object is to avoid the removal of the renal ganglion. The best method for removal he thought to be by laparotomy. He had removed the kidney three times and two patients died.

Dr. A. M. Owen, of Evansville, did not favor laparotomy.

Dr. Mudd, in replying, said that post mortems had shown for a number of years that one kidney was sufficient. If one is destroyed we have a hypertrophy of the other. That nephrotomy was proper before nephrectomy he thought would go without saying. We may have extravasation of urine and it may remain in the kidney for some time without inflammation resulting.

ABSORPTION OF WATER BY THE COLON

was the subject of a paper by **Dr. G. J. Cook**, of Indianapolis, which was dealt with in a very interesting manner.

Dr. A. M. Owen, of Evansville, Ind., had made experiments by injecting water into the rectum and had it to come away by the bladder.

Dr. C. S. Bond, of Richmond, asked if the urine had been examined for urea. He thought the water drunk at the springs would do about as much good if drunk at home, if drunk in the same quantities.

Dr. J. M. Matthews, of Louisville, thought the subject a very original one. Impactions which he has found were in the sigmoid flexure, not in the rectum. The injection should be made at this point.

CHRONIC PHARYNGITIS

was the subject of a paper by **Dr. Townsend Porter**, of St. Louis. He gave some interesting vivisection experiments on two cats to show how the application of cold to the abdomen would cause a pallor of the mucous membrane of the trachea, which in his experiments was exposed to the view of the assembly. The experiments were first performed by Dr. Rossbach, of Würzburg, Germany.

PENETRATING ULCER OF THE INTESTINE

was the subject of a paper by Dr. J. M. Emmert, of Atlantic City, Ia.

LAPAROTOMY WITH CASES

was the subject of **Dr. H. C. Dalton**, of Missouri. The justifiability of laparotomy has long since been acknowedged. Appendicitis, perityphlitis, peritonitis, gunshot wounds of the abdomen are conditions which demand this operation frequently. He had used Senn's hydrogen-gas injection with success. In one case of gunshot wounds of the abdomen he had fifteen perforations of the abdomen. He reported sixteen cases, and was sure that he would have had a better result had he operated earlier.

BENIGN LARYNGEAL GROWTHS

was the subject of a paper by Dr. William Porter, of St. Louis.

CONSANGUINEOUS MARRIAGES

was the title of a paper by **Dr. A. W. Spain**, of Terre Haute, Ind. He claimed that the physical condition of the persons married was solely responsible for the peculiarities of the offspring, and the fact that they were blood-related had nothing to do with the case.

CAN A DISEASED FALLOPIAN TUBE BE TREATED THROUGH THE UTERUS?

was treated affirmatively by **Dr. T. B. Harvey**, of Indianapolis. He referred to Cincinnati, Kansas City, and Dublin writers who had been inclined to hold him and his treatment in this line up to ridicule and related his early experience with the mode. He read a paper on this subject before the Tri-State Medical Society in Indianapolis in 1883. The physiology and pathology of the oviducts he hoped would be more thoroughly studied when attention was directed to this subject. He quoted from Barnes, Thomas, Winckle, Bandl, and Fritz on this subject, the quotations being favorable.

THE RECENT EPIDEMIC OF SMALL-POX AT MOBERLY, MO.,

was the subject of a paper by **Dr. Joseph Grindon**, of St. Louis. This was an interesting paper on an interesting epidemic which spread from the opening of an old chest of second-hand clothing brought from Bohemia by an emigrant. He said it was the opinion of the secretary of the State Board of Health that we would have small-pox in Missouri this winter. He had the cases all nicely tabulated into generations on a chart, which also showed two interesting points, the effect of isolation and the very low death-rate—only 6.25 per cent. Some interesting points on the effect of vaccination were also brought out.

A TYPICAL CASE OF MASTOID DISEASE

was the subject chosen by **Dr. S. S. Beard**, of Chicago, and handled in a thorough and entertaining manner.

A YELLOW-FEVER MANIFESTO

was the result of a discussion on the subject of yellow fever, introduced by a paper read by **Dr. C. G. Comegys**, of Cincinnati. The whole matter was referred to a committee consisting of Drs. George Homan, of St. Louis, J. A. Larrabee, of Louisville, J. D. Griffith, of Kansas City, George N. Kreider, of Springfield, Ill., G. A. Collamore, of Toledo, O., David S. Booth, of Sparta, Ill., A. U. Williams, of Hot Springs, Ark., and A. P. Waterfield, of Tennessee. These gentlemen were instructed to draft resolutions embodying the sense of the Association on this subject. The resolutions were adopted by unanimous vote without discussion.

Resolved, That it is the sense of this meeting that yellow fever is not contagious in the ordinary sense of the term; that it cannot be communicated from the sick to the well, except in an atmosphere containing germs.

"That the mildness of the present yellow-fever invasion and the lateness of the season warrant us in strongly deprecating the fear now existing in many Southern communites, the present rate of mortality not being greater than that which ordinarily obtains in typhoid fever.

"That the self-imposed quarantine regulations now in force in the States north of the infected districts are not only absurd but inhuman, and unworthy of the age in which we live.

"That the quarantine regulations, to be effective, should apply to the baggage, clothing, and effects, rather than to the person of the individual.

"That when such effects come from infected districts, they should be destroyed by fire, and the owner reimbursed from public funds.

"That cities and towns to the north, and upon lines of travel, may safely provide hospitals for the reception and care of the sick."

The resolutions were signed by the members of the committee.

A PLEA FOR SIMPLER THERAPEUTICS

was the subject treated by **Dr. Thackery**, of Chicago.

Dr. J. A. Larrabee, of Louisville, thought we were in greater danger now from poly-pharmacy than anything else. The old prescription of calomel and jalap is now very rarely prescribed, and there is nothing more beneficial than this, especially in this Southwestern country. Emetics are seldom prescribed now, yet the therapeutic effect of these things remains the same.

PRACTICAL POINTS IN DENTISTRY

for the general practitioner was the subject discussed by **William Conrad, M.D., D.D.S.**, of St. Louis. He considered dentistry to be one of the legitimate specialties of medicine. He thought there was need for greater familiarity on the part of the general practitioner in regard to dentistry. He recommended that the teeth be brushed on every surface every day, and that picks be used after each meal. The powder used should be precipitated chalk. He thought that men who advertised gas should be discountenanced, as it leads to the sacrifice of good teeth in a great majority of cases. Physicians should recommend dentists who follow the code. Fraternizing of physicians and dentists is necessary, and will result in benefit to all.

The discussion which followed dealt mostly with the implantation of teeth. **The President** recited the implantation of teeth done by John Hunter.

Dr. Conrad, in replying, defined the terms transplantation, implantation, and replantation.

THE SURGICAL TREATMENT OF FRACTURE OF THE PATELLA

was the subject of a paper by **Dr. F. J. Lutz**, of St. Louis. He illustrated his report clinically, and was sorry to state that one of his best cases, a female, had suffered one of those reverses of fortune, and got confined in the workhouse. Owing to the absence of the proper official, looking after his political fences, that executive clemency which would allow him to present her there could not be obtained. He reviewed the causes of partial anchylosis. The operation was made after Fluor, of New York. A transverse incision is made, cutting down on to the tissues of fractured bone. He presented two propositions: 1. The osseous union of the fractured patella is desirable and necessary for the re-establishment of the functions of not only the knee but also of the entire limb; 2. Arthrectomy accomplishes this end with the smallest loss of time, with the greatest certainty, and, if performed under proper wound treatment, is not *per se* a dangerous surgical procedure.

CLINICAL NOTES ON RHEUMATIC NEURALGIA

was the subject of a paper which was extensively discussed by the members. It was read by Dr. R. F. Brooks, of Carthage, Mo.

Dr. Chapman, of Toledo, O., said he was a man of perfect health, but had frequent recurrences of lumbago which he could not cure.

Dr. Simson, of St. Louis, recommended massage.

Dr. Owen, of Evansville, Ind., recommended cupping.

Dr. Smith, of Vincennes, Ind., treated this complaint with carbonate of iron, the hot iron, and sweat-baths.

Dr. Pitman, of Jacksonville, Mo., said he thought we should not say that we could not do anything in this climate. In spare and lean patients he thought it due to a fault of nutrition.

Dr. Joseph Grindon, of St. Louis, Mo., said he had used ichthyol externally with success.

Dr. J. A. Larrabee, of Louisville, thought the trouble due to a want of oxidization of the products of nutrition.

The discussion was continued by Dr. Lowe and Dr. Bond, of Indiana, and closed by Dr. Brooks.

PSYCHICAL TREATMENT OF THE INSANE

was the subject of a paper by Miss Bryant, of Chicago. She once heard a patient say that every superintendent of an insane asylum should be confined in the barred room six months before allowed to continue his position. He would then know better how to treat his patients. This room the patient described as hell. She discussed the insane atmosphere which was present in asylums. The personality of attendants she thought very great in importance. She advocated the cottage plan of asylums, dispensing entirely with the enforced confinements, and recommending humane treatment throughout.

Dr. Chapman, of Toledo, O., said that he had considerable experience with the treatment of the insane. He liked the cottage plan very much. The cottage asylum at Toledo was a home, not a prison. The patients were put in cottages of not more than thirty each, and treated as human beings.

Dr. Shaw thought the freedom given insane patients had gone far enough. It was now time to call a halt, or we would have a very severe reaction.

The paper was discussed by several other gentlemen.

THE YELLOW-FEVER QUESTION AND QUARANTINE

was discussed at great length by Dr. J. R. Rauch, Secretary of the State Board of Health of Illinois. He condemned quarantine as existing at the present time in the most severe terms. He stated that the yellow fever cannot spread in a continued temperature of seventy degrees or under, and the present panic was uncalled for. There was no danger at all above the North Tennessee border. He condemned the inefficiency of local quarantine. The address of Dr. Rauch met with sincere approval, and the Association elected him chairman of a committee to investigate the question.

Several other papers were read in abstract or by title, and the Association adjourned, to meet in Evansville, September, 1889.

Antiseptic Value of Chloroform.—Dr. Salkowski writes to a Vienna medical journal concerning the use of chloroform for the preservation of samples of urine by the analyst. A six-per-mille solution was found by him to effectively prevent the growth of micro-organisms, and he recommends it to be employed for keeping pathological liquids, and for the storage of anatomical preparations. Moreover, he suggests the employment of such a solution internally as a disinfectant and as a mouth-wash, and observes that it could be advantageously added to solutions for hypodermic use.—*Medical Press*, June 6, 1888.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department. United States Army, from September 30 *to October* 6, 1888.

Williams, John W., Major and Surgeon, on duty with battalion of 2d Artillery, now at Fort Wadsworth, New York Harbor. Granted leave of absence for one month, with permission to apply to the proper authority for an extension of one month. Par. 1, S. O. 209, Headquarters Division of the Atlantic, Governor's Island, New York City, October 4, 1888.

Cronkhite, Henry M., Major and Surgeon. On being relieved by Captain Corbusier, will report for duty to the Commanding Officer, Little Rock Barracks, Ark., reporting by letter to the Commanding General, Division of the Atlantic. Par. 10, S. O. 227, A. G. O., Washington, September 29, 1888.

Adair, George W., Captain and Assistant Surgeon. Is relieved from duty at Fort Brady, Mich., and will report for duty to the Commanding Officer, Fort Robinson, Neb., reporting by letter to the Commanding General, Department of the Platte. Par. 10, S. O. 227, A. G. O., Washington, September 29, 1888.

Corbusier, William H., Captain and Assistant Surgeon. On being relieved by Captain Taylor, will report in person to the Commanding Officer, Fort Hays, Kan., for duty at that post, relieving Major Henry M. Cronkhite, Surgeon, and reporting by letter to the Commanding General, Department of Arizona. Par. 10, S. O. 227, A. G. O., Washington, September 29, 1888.

By Direction of the Acting Secretary of War, the following named officers of the Medical Department will report in person, on the dates set opposite their respective names, to the President of the Army Medical Examining Board, Army Building, New York City, for examination for promotion: Captain James C. Merrill, Assistant Surgeon, October 16, 1888; Captain George McCreery, Assistant Surgeon, October 16, 1888; Captain Richard W. Johnson, Assistant Surgeon, October 9, 1888. Upon completion of their examination the officers named will rejoin their proper stations. Par. 5, S. O. 231, A. G. O., October 4, 1888.

Taylor, Arthur W., Captain and Assistant Surgeon. Is relieved from duty at Fort Robinson, Neb., and will report in person, without delay, to the Commanding Officer, Fort Grant, Ariz. Ter., for duty at that post, relieving Captain William H. Corbusier, Assistant Surgeon, and reporting by letter to the Commanding General, Department of Arizona. Par. 10, S. O. 227, A. G. O., Washington, September 29, 1888.

Rafferty, Ogden, Lieutenant and Assistant Surgeon. Will stand relieved from duty in connection with the Division rifle competition, the 7th inst., and under Par. 6, S. O., No. 2, c. s., Headquarters Division of the Missouri, will return to his proper station, Fort Clark, Tex. Par. 5, S. O. 95, Headquarters Department of Texas.

Official List of Changes in the Medical Corps of the United States Navy for the week ending October 6, 1888.

Hudson, Adrian, Medical Inspector. Ordered to Naval Hospital, Mare Island, Cal.

Gihon, A. L., Medical Director. Detached from the Naval Hospital, Mare Island, Cal., and proceed home.

Remedy for Warts.—Kaposi recommends one part of bichloride of mercury dissolved in thirty parts of collodion. A little of the solution is painted on and around the base of the wart once every day.

PNEUMONIA—ITS INCREASING DEATH-RATE. ONE OF THE ESSENTIALS IN ITS TREATMENT.

BY GOUVERNEUR M. SMITH, M.D.,

NEW YORK CITY.

WHATEVER doubts may be entertained regarding the specific cause of acute lobar pneumonia, there is no doubt in respect to the seasons of the year in which the disease is most prevalent in this latitude. The subjoined table, kindly furnished me by Dr. John T. Nagle, Register of Vital Statistics in this city, clearly demonstrates the ebbings and floodings of a diseased tide, as it has disastrously flowed for the past decade through the calendar months of each year of that period.

Deaths from Pneumonia in New York City, by Months, etc.

Years and months.	1887.	1886.	1885.	1884.	1883.	1882.	1881.	1880.	1879.	1878

A glance at the table shows that the autumn, and specially winter and early spring, are in deadly alliance with the disorder. History is doubtless to repeat itself; and it requires no preternatural gift to prophecy that in many homes Christmas cheer, and New-Year and Easter greetings, now anticipated with pleasure, are to be interrupted by the ghastly intrusion of pneumonia.

Meteorologists classify the month of March in the vernal season, and, scientifically, it appears as a harbinger of flowers. Popular classification does not yield it any meed of praise as such a harbinger, but ranks the month as a ruthless, cyclonic Juggernaut. An inspection of the above table illustrates its mortal greed. There seems to be an untimely hitch between the meteorologists and the ordinary run of climatological observers.

With such important facts before them, it behooves physicians at all times, but specially each autumn, to examine their equipments, and find if they can improve their methods of smiting a disorder which annually proves such an inimical foe to mankind. The disease not only prevails extensively during the seasons designated, but also prevails most disastrously, its rate of mortality reaching a very high figure. The physician of to-day, when in attendance upon a case of pneumonia, is perplexed with anxiety in regard to the result; and consternation and dismay unnerve both the patient and the family. Such intense solicitude and affright are modern concomitants of the malady. A few decades ago the disease, while considered as a serious one, was not regarded with such appallment. Medical science has in many directions been making advancements in pathology and therapeutics, but so far as pneumonia is concerned, science has shrivelled, and the rate of mortality from the disorder has been increasing. This is an unpleasant fact to acknowledge, but it is, alas! too true.

Dr. Henry Hartshorne, in his paper read before the College of Physicians of Philadelphia, February 1, 1888, has so ably laid before the profession his views on the "Past and Present Mortality and Treatment of Pneumonia," that it is only necessary to briefly allude to the statistics he has gathered in relation to the subject.

In the Pennsylvania Hospital he has found that the death-rate from the malady has augmented from 6¼ per cent. in the years 1845–46–47, to 18½ per cent. in the years 1865-66-67, and to more than 31 per cent. in 1884–85–86. He quotes from an editorial in the *Medical News* of December 11, 1886, that "the rate of mortality" of pneumonia "in the large general hospitals in this country is rarely below, more often above 25 per cent., which represents about the average death-rate from this disease in the Northern and Southern armies during the Civil War." It is added that "in this country extensive statistics of pneumonia in private practice are not available; but in the recent returns of the Collective Investigation Committee of the British Medical Association, the mortality was 18 per cent." Dr. Hartshorne continues: "This last ratio, it will be perceived, is considerably more than double the carefully computed mortality of pneumonia before 1858, namely, 8.33 per cent. We have thus, I think, a *demonstration* of the large increase in the proportion of deaths from that disease, in recent times, over what it was thirty, forty, and fifty years ago."[1]

New York experience corroborates the statistics of Philadelphia. Mr. Joseph H. Vandervoort, Assistant Librarian of the New York Hospital, has kindly furnished me with a table showing the number of cases, the number of deaths, and death-rate from pneumonia, occurring in the institution for a period extending from the year 18[illegible]0 to 1887. As divided into decades, it appears from the table that the lowest mortality occurred between the years 1820 and 1830. The mortality has been rising, and during the last decade it reached its acme, considerably over double the earlier percentage.

Any one at all familiar with metropolitan hospital affairs, distinctly understands that hospital statistics cannot always be quoted as exemplifying the results of treatment unless the cases are classified. Many cases of sickness and injury are brought to a hospital in a moribund condition; treatment can scarcely be initiated, and so far as the institution is concerned, they are really coroners' cases. Formerly, ships on arriving in port discharged their damaged and diseased crews into the wards of the New York Hospital; but, alas! too often in a plight kindred to that of perishable freight after a prolonged voyage. The modern hospital ambulance system, which is such a blessing to humanity, is doubtless often employed to foist into an infirmary, dying cases. Many without friends, in lodgings, or among heartless friends or relatives, are shuffled to an institution to die, while in their last moments. Even if too late to be placed under regular treatment, such unfortunates, fortunately, find a final crumb of comfort—medical skill palliates suffering, trained nurses minister with gentleness, adieu to life is peaceful, euthanasia affording quiet birth into eternity.

---

[1] The Medical News, Philadelphia, April 7, 1888.

Hospital statistics, therefore, in order to afford valuable scientific data, must be silted, and classified in groups of cases. Without any such general and accurate figures to guide, as relating either to hospital or private practice in this country, but from such sources of inference as are at hand, and from observation, it is now an accepted fact that the death-rate from pneumonia is much greater at present than it has been hitherto. Science and pneumonia have ever been at loggerheads, and the latter is vanquishing its pretentious foe.

Before coming to speak of the special point in treatment to which I wish to refer in this paper, a few initial thoughts may be appropriately interjected. It seems very conundrumical that so little use and mention are now made of means of relief which were formerly employed in the management of pneumonia, when it was a less deadly disorder. Fashion seems to have ostracized certain remedies and resources which apparently, at least, were benign in their action. The remedies were of modest chemical nature, as compared with their modern *élite* successors, but were, nevertheless, to the pharmaceutical manor born. Shoddy has undoubtedly in some instances superseded worth.

The use of the thermometer in disease has proved of great value in science, but since the abnormal rise of temperature has been specially noted, there has risen in therapeutics a potent fire brigade, known as the Antipyretics. This brigade has a formidable enginery, and has largely supplanted the older febrifuges. The latter had some engines, which had to be used with great caution, but a number of them could be employed to refresh patients without the slightest risk of inducing mischief.

Metropolitan fire departments are splendidly equipped to master conflagrations. Alert insurance patrols are always on hand, however, not to quench flames, but to protect property from being destroyed by the zealously-delivered deluge of the firemen. In medicine we have no equally alert protective insurance patrol—a puissant antipyretic, while quenching abnormal heat, may also extinguish the vital spark.

In the present fashionable catalogue of remedies are found oxydimethylchinizine, and phenylacetamide or acetanilide. These potentates figure aristocratically when associating with chemical companions, each syllable being a conferred degree of respectability, but when herding with drugs they appear each under a democratic alias, the former being known as antipyrine and the latter as antifebrine.

How do these and other modern and *élite* syllables behave in the human economy as they whirl through the blood in accord with the cardiac rhythm? The ghost of Holbein suggests a "Dance of Death!" The ghost is as satirical as his old prototype, but while the suggestion may be a vile innuendo, it nevertheless points to the necessity of extreme caution in exhibiting powerful remedies until after the most judicious observation such drugs are found to be thoroughly reliable in safety and efficiency. Medicine has always been handicapped by its laggard branch of therapeutics. Chemistry has presented to science choice remedies, and is to bestow others vastly more valuable, but it must be remembered that among the originalities of the chemists an article may appear as a "Jekyll" on the shelf of the laboratory and as a "Hyde" on the counter of the apothecary.

Recognizing the uncertainties attendant upon the use of drugs in the treatment of disease, it behooves the physician to place his patients, so far as it is possible, under the best hygienic conditions favoring recovery. Expectantly treating diseases under such circumstances is often most salutary. Lightning in summer strikes with a deadly celerity, and the chills and blizzards of winter smite the young, the feeble, and the old with almost equally rapid and ghastly strokes. Quite a number are so violently overcome as to succumb without an opportunity being offered for efficient medical interference; but quite a large proportion of cases of pneumonia are met with, in which it is reasonable to anticipate an acute illness of about ten days.

People in health with two lusty lungs must breathe about eighteen times a minute to maintain the blood in a pure condition. Suppose, for a moment, that it was possible in a healthy person to plug a part of one lung, or an entire lung, or a portion of both lungs, in such a manner that the air could not enter such occluded parts. Suppose such condition was continued for a period of from seven to ten days, what would be the plight of such an individual at the end of this period, if the closed part of the lung was of any considerable size? Nature would probably try to adapt means to meet the situation; but nevertheless the sound person would become a patient, from a mechanical cause, and would show signs of suffocation, hebetude, and heart-failure.

In pneumonia we find a somewhat analogous state. One lung, a part of one lung, or of both lungs are involved in disease; engorgement, and hepatization, rendering such portions of the pulmonary tissue, for the time being substantially useless for respiratory purposes, and neighboring portions are inclined to be cross and irritable. Complicating the situation, we find fever, more or less intense, and the abnormal heat frets the economy. Kidneys peevishly perform their work, springs, feeding the smaller and larger glands run dry, and scorched nervous centres rebel. Co-operative disquietude is manifest in every vital atom, and, unless assuaged, a communistic strike, chaos—ashes to ashes!

Amid the bedlam, varying in degree with the extent of the initial lesion and collateral sympathy, one strong hope can animate the physician. In the natural course of events the pulmonary obstruction will disappear in a few days, and the lung or lungs gradually resume normal work. Can the patient be bridged to reach the climax? Can the uninvolved portions of the lungs respire sufficiently to maintain a tolerable condition of the blood until the critical period is passed? This is the great exigency—this is an absolute necessity.

It is clear that the blood requires aëration; can it be revived in any manner so efficiently as through the lungs, nature's method of arterialization? Can pill conceal oxygen, and smuggle through the gastric pouch life to the venous circulation? Can essence of ozone be given to substitute the process of respiration? Can any zephyred antipyretic essentially promote hæmatosis? Resources there are to palliate pain, relieve thirst, abate fever, and stimulate flagging energies; and all important as these means are, they are almost insignificant as compared with affording pure air in superabundant quantity. While fresh air is essential in the management of all diseases, it is omnipotently indispensable in pneumonia, where the patient is using but a part of the breathing apparatus in the place of two lungs. It is more than ordinary ventilation that is required in such cases; what is needed is a persistent, systematic attention to a constant change of air in the apartment of the sick, by night, by day, each hour, each minute, and each second, and the twin companion of each one who enters the sick room should be a volume of genial, pure air.

Attention in the line above indicated should be excessive. Is such excessive care ordinarily bestowed upon the invalid? Trained nurses and affectionate relatives, while in a general way attending to ventilation, are contriving dishes, and with gentle hands administering comfort. But while with sympathetic smiles they may hope to cheer, and with kind words may encourage, their lungs are robbing the air of the apartment of its oxygen, and are vitiating the atmosphere. Friends, unwittingly, assume the rôle of foes. Sacred history records that when man was first formed the Creator "breathed into his nostrils the breath of life"—kindred and attendants clustered around a loved one, with the beneficent intent of preserving life, are breathing into his nostrils *the breath of death.* This need not necessarily be so. Freely admit the invisible friend, fresh air; it may as grandly revive the body, as the invisible Spirit often brightens the soul under the same circumstances.

I have purposely omitted giving details in relation to the therapeutical management of pneumonia, wishing to confine my remarks to one point in its care which is imperative. I will not even venture to suggest methods of perflation, as rooms, and suites of apartments, according to their size, situation, etc., may have to be managed differently to secure the requisite result. The open fire prevents aërial stagnation. The sick-chamber should be kept at an invariable and genial temperature, agreeable to both the patient and attendants. In admitting pure air, perceptible cool currents are to be specially avoided. Eastern philosophy deftly says "drafts of air are arrows of death."

It is a very, very difficult task to secure the all-essential aërial purity, but without it the patient is liable to suffocation and to heart failure. Here an opportunity is afforded for ingenuity on the part of the physician and family; and when plans are devised for attaining such result, they should be specially intrusted to vigilant attendants, whose sole duty, if necessary, it should be to unremittingly carry them out.

I am tempted, and will venture, to make a digression, and give a hospital reminiscence of student life, which will illustrate a past and popular mode of managing the disorder, a method probably pretty generally in vogue at that time. In those days, it was customary to give clinical bed-side instruction in the wards of the New York Hospital, groups of students following the attending physician. Circles of two or three were selected to auscultate each patient, thus the invalid was not fatigued and each disciple, in rotation, trained his ear to morbid sounds. The preceptor stated the stage of the disease, what was to be heard, foretold what was to be heard hereafter, and laid out the plan of treatment. The pupil did not learn that the disorder was extraordinarily fatal, and did not expect, on returning a few days later, to hear that the patient had succumbed, and to find the bed tenanted by another.

What means were then employed in treating the malady? Venesection, for the most part, had become obsolete. Wet and dry cupping and leeches were employed, as indicated by the condition of the patient. Poultices and oil-silk jackets were applied, and blisters were sometimes resorted to. In sthenic cases, minute doses of tartar emetic were exhibited, and in others spiritus Mindereri was given as a cooling draught, to which was added occasionally minute quantities of powdered ipecac. to relax the skin and loosen pulmonary secretion. Dover's powder allayed pain.

In no inconsiderable number of cases, mercury seemed as a sheet-anchor. Calomel in small doses, and guarded with opium, was administered at frequent intervals. The patient rapidly came under its influence. The dry mouth and tongue became moist, salivation was avoided beyond a genial moistening of the mucous membrane of the buccal cavity, which seemed also to extend to the vesicular structure of the lungs. On applying the ear to the chest, over the consolidated lung, one could hear it melt. Softened and loosened pulmonary secretion was freely expectorated, air again penetrated the lungs, and the ejection of sputa was favored by the use of Stokes' expectorant, with its stimulating carbonate of ammonia. While such remedies were being employed, fresh air, good food, and cordials, as required, were acting "*cito, tuto, et jucunde.*"

This reminiscence is given as a remembrance of bygone days, now sped a score and more of years. It is not presented with a view, either of urging an adoption of a plan of treatment, or of contrasting such plan with methods which have since prevailed, or of debating the question of varying types of disease, etc., for the limits of this article forbid any discussion of such important subjects. It is simply recorded as an historical fact; there was no doubt regarding the diagnosis, and the death-rate then was a little more than half of what it is at present.

In finally resuming the thread of my theme, it may be said that if physicians, while modifying their views regarding the methods of treating pneumonia, as it appears under varied phases and conditions, have failed to find infallible remedies for its relief, it is important that in one essential hygienic point of treatment, they can at least agree. An agreement, founded on truth, can remain an eternal covenant.

Further reiteration seems unnecessary; but a few words in closing. It is clear, from what has been said, that in the treatment of pneumonia a superabundance of pure air is specifically indicated. The patient's breathing apparatus is only partially performing its functions, as the diseased parts of the lungs are substantially useless. The working portion must perform the work of two lungs, for a week or ten days, in order to maintain the blood in a proper condition to sustain life. The patient requires purer air and vastly more air than one in sound health. In estimating the amount of genial, and possibly moistened, air which should gently and freely pass through the sick-chamber, allowance should be made, both for the requirements of the patient and for the requirements of attendants. The latter should be as few as possible, in order to lessen the chances of aërial contamination.

Our atmosphere at times is harsh, but it always contains a life-giving element. When exposed to its inclemencies, care must protect from its bitterness, while extracting its sweetening oxygen. When admitted to homes, it can be artificially tempered as a boon to the shorn and to the unshorn. While remedies often behave benignly in the human economy, nevertheless, pure air, as a remedial agent in the management of pneumonia and of other disorders, both acute and chronic, has ever been a more important ally of therapeutics than any panacea offered by alchemy or any hobbledehoy presented by modern chemistry.

Physicians will constantly meet with cases where, owing to the surroundings of the patients, it is impracticable to carry out the best methods of treatment. If a physician, however, through inadvertence on his part, allows a patient to die from want of fresh air, he deserves a stigma as ignominious, if not as heinous, as that which four centuries ago attached itself to Richard, Duke of Gloucester, for the crime of smothering princes in the Tower of London. History hisses through the ages!

THE ETIOLOGY OF RHEUMATISM CONSIDERED FROM A BACTERIAL POINT OF VIEW.—Dr. Mantle (*British Medical Journal*) points out that there are certain conditions of the body alike favorable to the development of rheumatism, scarlatina, and erythema nodosum. This, he says, argues that all these diseases are brought about by a similar poison. Holding these views, he set about making investigations in rheumatism. A dram of serum was withdrawn, under the strictest antiseptic precautions, from the knee-joint of a patient suffering with acute rheumatism. With this serum several sterilized tubes of gelatinized meat-infusion were at once inoculated, and in each tube a copious growth took place. He had found two kinds of bacteria—a micrococcus and a small bacillus. Cover-glass preparations of blood and serum showed micrococci as single cocci or pairs, and in acute cases zoöglea masses; in addition, small, short, thick bacilli were also seen, either single, in pairs, or in colonies. These bacteria were easily stained with methyl-violet, with fuchsine, or by Gram's method. In two cases of purpura rheumatica he found no bacilli. In one case of gonorrheal rheumatism bacilli were found only in the blood. In chronic rheumatism and rheumatoid arthritis the bacteria were found. Might not the chemical products of these bacteria be lactic acid and thus form the chief ptomaine of the diseases? The author found that cultivations of the bacteria of rheumatism, amygdalitis, erythema nodosum, and scarlatina, produced lactic-acid fermentation in sterilized milk.

CHRONIC JOINT DISEASES AND CONSTITUTIONAL TREATMENT.[1]

By V. P. GIBNEY, M.D.,

SURGEON-IN-CHIEF, HOSPITAL RUPTURED AND CRIPPLED, AND PROFESSOR OF ORTHOPÆDIC SURGERY, NEW YORK POLYCLINIC, ETC.

I HAVE selected the above title in order to bring before this Society of Practitioners a subject upon which there is a diversity of opinion and, at the same time, a certain amount of confusion.

The exact meaning of constitutional treatment is not clearly defined. When the surgeon who has much to do with joint disease is asked what his special management is, the practitioner usually follows this question by the following: "And do you employ any constitutional treatment?"

In former times, when scrofula played such an important part in the etiology of joint diseases, constitutional treatment was regarded as necessary to the full and complete management of a case.

By chronic joint disease, I would have you understand such affections as Pott's disease, hip disease, and white swelling. In view of the frequency of these ailments during early childhood and youth, I propose, this evening, to limit the discussion somewhat to the above affections as they occur in youth. I make no apology for defining white swelling as a tuberculous ostitis of the epiphysis of the knee-joint; hip disease as a tuberculosis inflammation of the bones entering into the formation of the hip-joint; of Pott's disease as a similar form of inflammation confined to bodies of the vertebræ.

Orthopædic and general surgeons of the present day seldom waste time in discussing the nature of struma or scrofula. There are some, however, who have for several years ignored these terms and held to the traumatic nature of joint lesions, and naturally find the initial processes in the soft parts. This theory, however, is not a popular one with the great majority of those who teach this subject.

Pathologists, with few, if any, exceptions, hold to the tuberculous nature of the diseases under consideration, and as a result of their studies we are enabled to locate the lesion in the immediate neighborhood of the epiphyseal line.

A prominent English writer has long since called attention to the similarity between chronic inflammatory lesions in the cancellous structure of the bone and like lesions in the parenchyma of the lung.

The two structures are not unlike, and the simile is well taken. A caseous focus in the end of the bone behaves very much like a caseous focus in the lung. By means of physical signs we are able to detect small areas of consolidation, or even small cavities with surrounding induration. Physical diagnosis does not help, however, in the diagnosis of bone lesions, but, on the operating-table and in the dead-house, exactly the same condition of things is often found in the cancellous structure of bone. The clinical histories of the two diseases are very nearly identical. Both have exacerbations, both may have long periods of remission. The interpretation of these exacerbations is pathologically as follows: A small inflammatory focus extends by continuity, in the case of bone, to the cartilaginous covering, and we have an increase of what are known as constitutional symptoms, and aggravation of the muscular spasm about the joint; in the case of lung-tissue, a rise of temperature, some distress in the respiratory symptoms, and an increase of the constitutional manifestations. If the inflammation extend beyond homologous tissue, we have what is known as inflammation by contiguity, and, in case of bone, the cartilage and synovial membranes are invaded, giving rise to true joint symptoms, and there may or may not be effusion into the joint.

In the case of the lungs we have the pleura invaded, and there may or may not be effusion. As the inflammation subsides the symptoms in the two cases abate, and convalescence may seem to be established.

The careful practitioner, however, understands this state of affairs, and does not permit himself to be misled by the wishes of the patient.

He knows that the tissues which have been recently inflamed are rendered more vulnerable, and he expects to find more impairment of the joint function and more impairment of the lungs after succeeding exacerbations. So long as we have, in these exacerbations, simply an extension of the inflammation by continuity and contiguity, we have nothing more than a simple serous synovitis in the one case and a pleuritis with adhesions in the other.

When this central focus has increased in size to the formation of an abscess-cavity, the synovial membrane and the pleura finally become walls of this sac, through which rupture takes place, producing in the one case a suppurative synovitis, and in the other a suppurative pleurisy.

It will be seen, from the foregoing, that chronic joint disease is secondary to chronic bone disease. In adult life, however, the rule is to have these relations reversed. Here we have chronic synovitis, chronic fungous arthritis, gelatiniform arthritis, etc.

I am prepared to admit that the practitioner finds in childhood cases of primary synovitis; at the same time, however, I must take the liberty of questioning his diagnosis if he employs the term chronic to designate the affection. Cases of acute traumatic synovitis are not uncommonly met with, just as cases of acute primary pleuritis are met with, in childhood. I am aware that a primary pleuritis is regarded by many as dangerous to the lung, and that, if resolution does not take place within a short time, a predisposition to pulmonary disease results. We have no such protection to the lung as we have to the cancellous structure of bone.

It must be remembered that there is a dense layer of compact bone-tissue immediately beneath the cartilage. I do not believe, therefore, that a simple traumatic synovitis predisposes to bone disease.

Let us return for a moment to those cases of so-called chronic primary synovitis and subject them to analysis. Occasionally I find a case that seems, at first glance, to be one of typical primary chronic synovitis. There is distention of the synovial capsule, and the mother avers that this swelling has only recently appeared, and that prior to this the child was perfectly well and free from lameness. Before the interview is completed, however, she admits that some six or twelve months ago there was some stiffness of the knee and impairment of gait which lasted a few weeks. No special importance was attached to it and he seemed to recover; but, on still closer investigation, it is discovered that the recovery has been perfect, so that to-day I am forced to admit that I have seen no cases either in private or hospital practice where the chronic joint disease started as a primary synovitis. Let it be distinctly understood that I am speaking of the disease as it occurs in childhood.

This much for the definition of the first part of my title.

What shall we understand by the term constitutional treatment? It is assumed that the constitution of the patient is impaired more or less, and that, whatever local treatment we employ for the joint disease, a special treatment must be adopted for the repair of the constitution.

When an interne of the Hospital for Ruptured and Crippled, I was taught to look upon drugs as a *sine qua non* to the successful management of all joint diseases.

All patients with joint disease were kept for months on the following prescription:

℞. Hydrarg. bichl.......................gr. ij.
Tinct. cinch. comp ....℥ vj.
M. Sig.—ʒ j., b.d.

In addition to this, they also had one drachm of pure cod-liver oil twice a day. During the summer months the cod-liver oil was omitted, and some preparation of malt substituted therefor.

---

[1] Read before the Practitioners' Society, October 5, 1888.

After a patient had been taking the bichloride and tincture many months, a change was made to the sirup of iodide of iron (gtt. x.), twice a day. With an occasional dose of calomel, the above was regarded as constitutional treatment.

In general practice, cod-liver oil and sirup of iodide of iron are looked upon as proper constitutional treatment.

Many physicians, I know, regard the phosphates in some form as necessary to the successful management of the case. Professor Jacobi believes that phosphorus is almost a specific in bone disease.

I claim to have administered faithfully the above drugs, and I must confess that I fail to see how it is possible to estimate their true value. Nearly all are given on what we choose to style general principles. The public seem to have an impression that medicine in some form must be administered, and, if the specialist fail to prescribe anything more than some form of apparatus, the family physician, in one way or another, intimates that the specialist is apt to be one-sided. It is my custom to prescribe tonics when I think a tonic is indicated: to counteract, by the few specifics we have, any of the vices to which the constitution may be subject—*e.g.*, if a specific element be present, I employ mercury and the iodide of potassium, either singly or in combination; if the system suffer from malarial poisoning, I use quinine; if a rheumatic element is found, I adopt such remedies as I think will counteract this influence. In all cases where any stomach or intestinal trouble is present I employ measures to improve the digestion.

I am sure the gentlemen present will concur with me when I assert that our aim should be to keep the general health at or above par. Believing, as I do, in the tuberculous nature of the majority of these lesions, I have come to look upon a change of air or climate as exceedingly important.

The time will come when we shall feel that it is as important to send our bone cases to the mountains, or to other health-resorts, as it is our pulmonary patients. The apparatus we employ, therefore, should be so simple that the patient can be taught the principles governing the same, and how to manage the dressing. I do not wish to be understood as advocating any lack of intelligent care on the part of the surgeon who employs the apparatus. The facilities for travel at present are so great that the patient can return at proper times for the adjustment of a new splint or the repair of an old one. A change of climate can thus be easily obtained and the general good of the patient enhanced.

Thus far, it will be seen, I have confined my remarks to the mechanical and the medical aspects of the subject. I cannot close these fragmentary remarks without alluding to the surgical features of chronic joint-disease.

If a bone-abscess exist, I know of no better constitutional treatment than the antiseptic evacuation of such abscess. We are all familiar with the prompt relief afforded the patient by the removal of diseased bone.

Dr. Yale, of this city, a few years ago, in a paper on excision of the hip-joint, stated that an excision was sometimes the best antipyretic one could employ. If, therefore, our patient is suffering from hectic, it seems unscientific to employ drugs for this condition when we can remove the cause by the knife. If suppuration is prolonged, we find a low specific gravity of the urine, which continues for some weeks. The best constitutional treatment we can give the patient is to remove the diseased bone, or even the offending member.

Lest my hearers may think that I am advocating operative surgery for all joint diseases, I would say that in protective splints I have found most gratifying results in by far the greater number of cases with which I came in contact. Take, for instance, a case of chronic ostitis of the hip (hip disease) where the patient is suffering from loss of sleep—that annoying symptom of reflex spasm. If we can immobilize the hip, or employ simple traction which practically immobilizes, I am sure we find this treatment better for the constitution than alteratives, opiates, or counter-irritants. If, furthermore, we can employ a portable apparatus which accomplishes the same results, we not only contribute to his comfort at night and his pleasure by day, but we place him under the most favorable circumstances for recovery. It is the duty, therefore, of the surgeon to employ such measures, and at the same time bear in mind that there are bone lesions that no form of splint will cure. While he should have a proper amount of respect for constitutional treatment, he should remember that the judicious employment of the knife will often accomplish more than all the drugs in the Pharmacopœia. As in pulmonary diseases we are accustomed to look upon a robust condition of health as the best evidence that our patient is improving, so in chronic joint disease we should look upon the physical condition as a fair index of the progress of the case.

Drugs, diet, and climate are recognized as potent factors in the building up of health, and if to these can be added the relief of irritation in or about a joint and the removal of such influences as contribute to sepsis, then our armamentarium is complete.

SHOULD INEBRIATES BE PUNISHED BY DEATH FOR CRIME?[1]

By T. D. CROTHERS, M.D.,
HARTFORD, CONN.

It is a common error to suppose that law and its practice, and the facts and theories of science generally accepted to-day, are final and fixed truths. The fact is not often recognized that theories, creeds, and laws, and their application to the events of life, are only human conceptions of truth. Hence the demand for change and readjustment of the relations of life to conform to the new truths and new facts constantly appearing. Whenever human conduct, thought, and law fail to adapt themselves to these new conceptions of life, great injury and loss follow.

The treatment of insanity, medically and legally, has totally changed from that of the past century. A better knowledge of such cases has demanded an adjustment of theory and practice to conform to the new views. The armies of the lawless and defective are no longer concealed by the fogs of superstition. Their origin and march are growing more and more distinct with every advance of the age. The hosts of the insane have been outlined and traced; the idiot has appeared as a growth from distinct causes; the epileptic has emerged from the theory of being possessed with an evil spirit; criminals are found who are not deceitful and desperately wicked, but the direct products of conditions of life and living; the inebriate, who for ages has been the subject of ridicule and punishment, comes into view as defective and diseased. Thus, from the front lines of advance come new facts, new views, requiring new laws, new adjustments of the theory and practice of yesterday to meet the clearer, wider knowledge of to-day. The farmer must put aside the old implements of his fathers; the merchant must use the telegraph and telephone because correspondence is too slow; the practice of the courts, the theory and treatment of diseases, the teaching from the pulpit, are all changing. The spirit of the age questions and demands reasons for the theories and practices of to-day. It inquires if our methods and theories are destructive or obstructive in the race march from the lower to the higher. My purpose is to show that the death penalty, as a means of punishment for inebriates, is opposed by all the teachings of science and experience, and should be superseded by other means based on a more accurate knowledge.

---

[1] Read before the New York Medico-Legal Society, September 12, 1888.

An outline view of the present legal methods of dealing with inebriates who commit petty crime will make clear both the destruction and obstruction which follow from the failure to comprehend and utilize the facts which science and experience teach.

Of the estimated half million inebriates in this country, ten per cent. are yearly convicted of crime of all degrees. Of this number, two per cent. commit capital crime, and one per cent. of this number, or about one hundred persons, are executed every year. These statistics are only approximate estimates, but they illustrate in a general way the extent of inebriety, and how far the courts are called to restrain and check it. A study of the local statistics shows that in every town and city of this country a large part of the business of courts of justice is the legal punishment of inebriates. The inmates of jails and prisons who are inebriates are variously estimated at from fifty to eighty per cent. of the whole number. Year after year the courts administer the same treatment of fine and imprisonment for both inebriety and crime, and yet the number of inebriates is increasing. When this fact is studied, it appears that a species of fatality seems to follow the first legal punishment of inebriates, seen in a repetition of the same offence and the same punishment, with an ever-increasing frequency. In the courts these are called "repeaters," and the number of sentences of the same man for the same crime in some cases extends into the hundreds. In one thousand cases confined on Blackwell's Island, nine hundred and thirty-five had been sentenced for the same offence from one to twenty-eight times before. This fatality seems to start with the first sentence and punishment; and the victim is precipitated lower and lower, becoming more degenerated and incapacitated, until finally death follows in prison, the insane asylum, or almshouse.

The natural history of such cases is continuous punishment for inebriety, assault, theft, burglary, and petty crime, and finally murder. Each period of punishment is followed by the same or more aggravated crime. The intent and purpose of the law is defeated, and this means of treatment both directly and indirectly increases crime and prepares the inebriate for worse and more hopeless states. The courts and prison officials are powerless, public opinion sustains the law and demands its execution irrespective of all consequences. The poor victims punished to-day reappear to-morrow, under arrest for the same or a worse crime. The severity of the punishment makes no difference. The inebriate who, under the influence of alcohol, commits assault to-day, will do so to-morrow, and next year, and so on, as long as his inebriety continues. No legal punishment of fines and imprisonment can stop him. These facts are sustained by the experience of all courts and prison officials. They are also equally true in the death punishment of inebriates for crime.

When the crime is the direct or indirect result of inebriety, it is only the natural outcome or logical result of conditions of brain disorder and surroundings. The assumption that inebriety is always a voluntary condition, within the control of the person, is a most fatal error. On this error is based the death penalty. Its practical failure is apparent in the increase of capital crime by inebriates. The inebriate who has been arrested for petty crime while intoxicated many times before, finally commits murder in the same condition, and is executed. His friends and companions do the same thing and suffer the same penalty. Thus one brutal murder committed in a state of intoxication is followed by another equally brutal, and the execution of the murderer makes no diminution in the number of similar crimes that follow. In every daily paper appear records of the same murders by inebriates under the same circumstances. A wave of public vengeance may dispose of the criminal by lynch law, or only be satisfied when he is hung, but the same murders are committed again by the same class of men. This is only the repetition of the same blunder of fining and imprisoning inebriates for inebriety and petty crime. In both cases the victims are destroyed, and similar offences are increased rather than diminished. In one case imprisonment and fines make the inebriate more incurable and less capable of change of life and living; in the other, the execution of the inebriate leaves a brutalizing, combative influence and a form of contagious glamor that defective brains are powerless to resist. These are the facts which experience and observation fully confirm, and which the latest teachings of science explain and point out.

To-day it is known that the action of alcohol on the brain and nervous system is anæsthetic and paralyzant. The use of alcohol to excess, at intervals or continuously, always numbs and paralyzes the higher operations of the brain; the over-stimulated heart reacts, and depression and feebleness follow. All the senses are disturbed and become more or less incapable of transmitting the impressions which are received. The brain is incapable of accurately comprehending the nature of acts and the relation of surroundings when under the influence of alcohol. The palsy which follows from this drug masks all brain action. Delusions of vigor and strength appear; events and their consequences and motives and conduct are all exaggerated, misconceived, and misinterpreted, and the brain is unable to correct them. The pronounced delusions, illusions, delirium, mania, imbecility, and stupor, seen in states of intoxication, are only the advanced stages of brain conditions which begin with the first glass of spirits. The early changed conduct and speech of men who use spirits are the first symptoms of the paralyzing action of alcohol. More spirits are followed by more paralysis, and finally all judgment and experience, and all distinctions of right and wrong, of duty and obligation, are confused and unreal. The supposed brilliancy which follows from the use of spirits is unreal and transient—it is the glamor of the mind which has lost its balance and is unable to correct itself. No other drugs are known whose paralyzing effects on the higher brain centres are so positive and insidious. The inebriate and moderate drinker have always impaired brain force and nerve power. The automatic nature of their life- and brain-work may cover up this fact; but change the surroundings and demands on the brain, and its incapacity appears. Every toxic state from alcohol more or less permanently impresses and debilitates brain integrity.

The fear of the law and consequences of acts make little impression in such cases. The brain is anæsthetized and crippled, and cannot realize events and their nature and consequences. The crime committed by an inebriate cannot be the act of a healthy brain. The more pronounced his inebriety and the longer its duration, the more positive the disease and incompetency to reason and control his acts. The effort to fix a point in all disputed cases where sanity and responsibility join insanity and irresponsibility, is an impossibility which every advance of science demonstrates. It is equally impossible to use alcohol to excess for years and have a sound. normal brain. It is impossible in such a case to fully realize the nature and consequence of acts and obligations. It is a legal fiction to suppose that a crime committed while under the influence of alcohol was the voluntary act of a sane man. It is a legal fiction to suppose that a sane man would plan a crime and then become intoxicated for the purpose of executing it. It is a legal fiction to suppose that premeditation in crime committed by inebriates is evidence of sanity and consciousness of his acts. These are some of the facts of science which bring additional evidence of the error of capital punishment in such cases.

A study of the crime committed by inebriates amply confirms the fact of brain incapacity and disease. Thus, in cases of capital crime by inebriates, delusions, illusions, morbid impulses, and epileptic explosions, are common symptoms. In many cases capital crime is the result of peculiar circumstances and sudden strains on the enfeebled brain, or the possession of a morbid impulse, a delusion, or illusion, that suddenly dominates the mind; also epileptic explosions, that are real attacks of maniacal fury and unreasoning. Alcoholic somnambulism or trance is present in many cases. The mind in these cases is oblivious to all outside influences or considerations, and is subject to every passing impulse that may come from either external or internal causes. At the time no general indications of unconsciousness may be present, yet a certain automatic line of conduct and history of crime give clear hints of brain enfeeblement. All crime by inebriates will be found associated with concealed or open delusions, morbid and epileptic impulses, and sense deceptions. In all these cases the brain is unsound and cannot act rationally and clearly. There are present in these cases either insanity of inebriety or the inebriety of insanity. The inebriety of the prisoner has merged into insanity, or some concealed insanity or brain degeneration has developed into inebriety or dipsomania. The death penalty to such cases has no horrors. It is rather welcomed. The struggle for life is the attractive publicity that makes a hero of the man, and the mystery of the end of life intensifies the interest to the last moment.

A summary of the facts we have outlined would sustain the following statements:

1. The legal treatment of insanity has changed in obedience to a more accurate knowledge of the brain and its diseases.

2. The legal treatment of inebriety is unchanged to-day. Although it occupies two-thirds of the time of courts all teachings of science and a larger knowledge of the inebriate and his malady are ignored.

3. The ruinous error of punishment by fine and imprisonment of inebriety, and petty crime associated with it, which notoriously increases and perpetuates the inebriate and criminal, is a fact demonstrable in every community.

4. Thus public opinion, through mediæval theories and laws, is training and preparing a class of inebriates who first commit petty, then capital crime, with a certainty which can almost be predicted.

5. The death penalty for such crime utterly fails for the same reason. The execution of any member of this class simply opens the door for an army already prepared and trained to take their places.

6. From a scientific study of these cases, it is clearly apparent that they are diseased and incapacitated to act sanely. Alcohol has palsied the brain and made them madmen. The very fact of continuous use of alcohol is evidence of mental impairment and unreasoning act and thought.

7. To hold such men accountable for their acts, and by punishment expect to deter them from further crime, and by such punishment check others from similar crime, is an error which both scientific teaching and experience point out.

8. The object of the State, through the law, is to protect society and the individual; but if the execution of the law-breaker fails to accomplish this end, the laws are wrong.

9. The unfounded fear that the plea of insanity in crime, and the failure to punish, is an encouragement for further crime, is flatly contradicted by statistics.

10. Among the mentally defective, the insane, and inebriates, the death penalty is followed by an increase rather than a diminution of crime.

11. The inebriate should never be hung for crime committed while under the influence of alcohol.

12. This method of punishment is never deterrent, but furnishes an attraction for other inebriates who commit similar crime in the same way, following some law of mental contagion.

13. The inebriate murderer should be confined the rest of his life in a military work-house hospital. He should be under the care of others, as incapacitated to enjoy liberty and incompetent to direct his thoughts or acts.

14. A change of public sentiment and law is demanded, and a readjustment of theory and practice called for. The criminal inebriate occupies a very large space among the armies of the defective who threaten society to-day, and his care and treatment must be based on accurate knowledge, not theory.

15. Inebriate murderers should never be placed on public trial, where the details of the trial are made prominent, or the farcical questions of sanity are publicly tested. They should be made the subject of private inquiry, and placed quietly in a work-house hospital, buried away from all knowledge or observation of the world.

16. The contagion of the crime and punishment would be avoided, and his services might repair some of the losses to society and the world.

TESTS FOR DIABETES MELLITUS.[1]

By PALMER C. COLE, A.M., M.D.,

NEW YORK.

Professor C. F. Chandler, of Columbia College, in 1874 brought from Berlin a modification of Fehling's test for the detection of grape-sugar in solutions, and determining the quantitative amount.

Dr. S. B. Ward, now of Albany, and myself, after long and carefully conducted experiments became convinced of its great superiority over any test with which we were then acquainted for the detection of grape-sugar in urine. In 1875 Professor Chandler read a paper on this test for sugar in urine before the New York County Medical Society, which, for some inexplicable reason, has remained ignored by the profession. Why a quantitative test so simple, so absolute, should be ignored by professors in Medical Colleges, and so far as I know, by all our text-books on urinary analysis, is difficult to account for.

Of all the tests for sugar Trommer's is the best known and most generally used by our profession. It is recommended in all the text-books, taught by all professors in our medical colleges and even by the professors in our polyclinics.

This test, so relied upon by the general practitioner (justified by the teaching of medical works and the lectures of those who should be a guide to the student), is untrustworthy.

It is untrustworthy for these reasons: Under certain circumstances, when urine contains grape-sugar, Trommer's test will fail to give the precipitation of suboxide or hydrated suboxide. Under such circumstances it is judicious, according to Seegen, "to filter the urine through animal charcoal one or more times until it is completely decolorized, to wash the charcoal with a little distilled water, and to subject this water to Trommer's test, which then, provided the urine originally contained .05 per cent. of sugar, causes a precipitate of suboxide of copper."—Ziemssen's Cyclopædia, American edition, vol. xvi, pages 974 and 975.

Under certain circumstances Trommer's test will give indications of sugar where none exists in the urine. This might possibly be obviated by filtering through animal charcoal, though I have never tried the experiment. Under any circumstances the proceeding is tedious and may lead to fallacious results, as I think it possible that the very process to which we subject the urine may cause a trace of sugar to appear where none previously existed. How many practitioners who use Trommer's test ever observe the above precautions? How many even know of the necessity for their use?

As long ago as 1854 Golding Bird, "On Urinary Deposits," American edition, page 295, says, "Several objections have been made to this test on the ground that mere uric acid is sufficient to reduce the copper, and thus introduce a serious source of fallacy." I would add that, when in excess, creatinin, ammonia, and sometimes the coloring matter of the urine will prevent the finding of sugar when it is present.

---

[1] Read before the Northwestern Medical and Surgical Society of New York, June 20, 1888.

For myself, I have been misled in previous years by finding by Trommer's test indications of sugar when probably none existed. My patients, after longer or shorter lapses of time, recovered. Knowing the ordinarily slow but sure progress of the disease, I was mystified, but concluded that diabetes mellitus was in some cases easily curable.

The modified Fehling's test showed me that the disease from which my patients recovered was probably not diabetes mellitus.

We have simple and infallible tests for the detection of grape-sugar in urine.

A test which, like Trommer's, may lead to fallacious conclusions should be expurgated from our text-books, and professors should cease to teach it to their pupils.

Fehling's test, if freshly prepared, may be relied upon. The one drawback to its use is its instability—on exposure to the air it deteriorates.

Professor J. C. Dalton obviated this defect by putting up the freshly prepared solution in half-ounce bottles, hermetically sealed, and opening a fresh bottle every time he made a test. Even with this precaution the test will sometimes decompose.

A modification of Fehling's test made up extemporaneously, perfectly trustworthy and reliable, uninfluenced by any of the normal or abnormal constituents of the urine, requiring no preliminary treatment of the urine (always an element of error), and by which a qualitative test can be made in five minutes, and a quantitative test in less than thirty minutes, is obviously superior. I am told that this test takes too much time to be applied by the busy professional man.

What professional man who takes an interest in his patients but can afford half an hour once or twice a week for the satisfaction of knowing absolutely their condition? The "differential density method" of Roberts, the fermentation test, the picric-acid test, as performed by Dr. Johnston, of London; the polariscopic test, and many others, all have sources of fallacy. The fermentative test is liable to these errors: In certain conditions of the urine it will fail to act when we know sugar is present. Again, the best prepared yeast, Fleischman's, will sometimes give us fermentation in water in which we know there is no sugar. The "differential density method" is liable to these errors and others. The precipitation of urates, earthy phosphates, and other changes not well understood lessen the specific gravity of the urine. As to the picric-acid test, our life insurance companies will not accept it. The polariscopic test, while no more accurate than the "differential density method" of Roberts, requires an expensive instrument which few doctors possess.

The limit of this article prevents the consideration of other tests, as I consider my test superior to any other.

During the last twenty-five years I have devoted much time to the specialty of urinary diseases. I have never found any test for grape-sugar so absolutely free from error as the one I have recommended.

Dr. Ward and myself, in the course of our experiments, spent one afternoon in Professor Chandler's laboratory. We had met with a specimen of urine which, by Trommer's test, gave indications of sugar, but with my test did not give sugar, but a deep yellowish-green reaction. We asked Professor Chandler what caused it? He said, "He did not know, but it was not diabetes."

After many months of clinical investigation I arrived at a conclusion from which I have never seen cause to vary. This peculiar reaction indicated a pseudo-glycosuric condition of the system, perhaps analogous to diabetes mellitus, with this vital difference—it was curable.

Shortly after arriving at this conclusion I had occasion to verify it. A prominent physician of this city, knowing I had long been engaged in examination of urine, brought me a specimen of his own. He had been pronounced diabetic by some of the best authorities in New York, was nervous and anxious, thinking and saying he had but a short time to live. He was preparing to give up his practice and move to the country, which he shortly afterward did.

When he called to get my report, I was pleased to tell him that I could not find a trace of sugar in his urine; that he did not have diabetes mellitus, but was suffering from glycosuria, which was curable, and that he would get well. He did not believe me. I said to him, "Perhaps your urine may be temporarily free from sugar, give me another specimen in two or three days." He did so; same result. I asked for and obtained a third specimen a week or ten days afterward, and again obtaining negative results I positively stated to him that he did not have diabetes mellitus and that he would recover.

He did not believe in my diagnosis or prognosis, and thinks to this day that he has recovered from a disease he never had.

I mention this prominent case as an illustration of the value of my test for diagnostic purposes.

Before proceeding further I would state that foods advertised as "Diabetic" are all, comparatively speaking, valueless, and so far as they advertise that they are absolutely free from starch, fraudulent.

With my test for the simple detection of sugar a large test-tube will suffice, but for a quantitative analysis the following simple and inexpensive apparatus is required: A retort stand, a few feet of rubber tubing, a Bunsen's burner, two or three Florence flasks of ten to twelve ounces capacity, one 100 c. ctm. flask, one 10 c. ctm. pipette, and a 25 c. ctm. burette graduated to tenths of a c. ctm.

The chemicals consist of, 1. A standard solution of sulphate of copper, C. P., 17.319 grams dissolved in 500 c. ctm. of distilled water. 10 c. ctm. of this solution will be reduced by .05 grm. of grape-sugar. 2. Caustic potash, C. P., one part dissolved in ten parts of distilled water. 3. Crystallized tartaric acid, C. P., pulverized. These reagents should be kept in grounds-toppered bottles.

All apparatus and C. P. chemicals can be obtained from Eimer & Amend, Eighteenth Street and Third Avenue.

The solutions are permanent. I prefer to make my own, and would advise others to do the same. With scales and metric weights and measures it is simple and easy.

To make the test solution: Take 10 c. ctm. of the copper solution, place it in a Florence flask and dilute with 40 c. ctm of distilled water (Croton water filtered, or rain water filtered after boiling is pure enough for all practical purposes), add and dissolve without weighing, a small quantity (.66 grm. is sufficient) of tartaric acid, C. P. (the only precaution to be observed is to use a sufficient quantity, which a few experiments will teach). Now add the potash solution until a deep and permanent blue is obtained. Place it on the retort stand to boil, for this test is only used while boiling. A spirit or kerosene lamp may be used instead of gas. The flask should be placed on a thin tin plate instead of wire-gauze to obviate smoking. It takes a few minutes longer to make the test but is safer.

This test is self-testing. If on boiling we get the slightest change of color, except, perhaps the intensification of the blue, we may rest assured that we have made some error in preparing our solution—our chemicals are impure, or our flasks are imperfectly cleansed. The solution, being worthless, must be thrown away and a fresh one prepared, which remains unchanged, before we proceed to test the urine.

After making a test, if sugar is found, the flask should be washed with eight or ten drops of nitric acid in a little water and then rinsed, to cleanse it from the precipitate of copper. While the test-solution is heating prepare the urine for analysis. Place 10 c. ctm. of the urine in the 100 c. ctm. flask, fill with water and mix. We have now urine diluted to ten per cent.

These dilutions are requisite for accuracy in quantitative analysis. Fill the 25 c. ctm. burette with the dilute urine. When the test-solution boils, add from the burette, drop by drop, until the blue is entirely discharged.

You have now a precipitate of the red suboxide of copper leaving the supernatant liquid clear. The reaction is *unmistakable ;* no matter what other reactions urine may give with this test, if the characteristic reaction of the precipitation of the red suboxide is not obtained, we may rest assured *that there is no grape-sugar in the urine.*

To determine the per cent. of sugar we have this simple formula: c. ctm. of urine used : grams. of sugar found : : 100 : per cent. of sugar.

For example, say we have used from the burette 7.4 c. ctm., then, as the urine used was diluted to ten per cent., we place the decimal point one figure to the left, and find that in reality only .74 c. ctm. of urine was used. Now fill out the formula .74 : .05 : : 100 : 6.756 per cent. of sugar. The urine used in this experiment had a specific gravity of 1.036. Knowing the amount of urine passed in twenty-four hours, a very simple calculation will show the amount of sugar eliminated from the system by the kidneys in a given time. The test is simple, cleanly, and reliable. Its delicacy is so great that the earliest stages of diabetes can be detected with the utmost certainty.

Any careful observer can detect one part of grape-sugar in five thousand parts of urine, and an expert may detect one part of grape-sugar in twenty thousand parts of urine.

For the last thirteen years I have used no other test for grape-sugar (though I have experimented with many) and it has never failed. The claim I make as the result of clinical observations with this test is the ability to diagnose between a pseudo-glycosuric condition of the system which is curable, and diabetes mellitus, which we all regard with grave apprehension, and in its advanced stages must consider, though amenable to treatment, as incurable. I say in the advanced stages, for I have had two patients who came to me in the early stages of the disease and were apparently cured. One, after being under treatment for eighteen months, remained well for ten years. The other was under observation for about three years after all traces of sugar had disappeared. I have seen neither since. These are the only two cases of recovery I have to report in thirteen years. Many cases have been reported as typical cases of diabetes mellitus cured, which, from their published histories I should call glycosuria.

I should class the conditions we have been considering, under three heads :

First, Pseudo-glycosuria. We are now unable by any known test to detect sugar, but have well-defined indications that serious changes are going on in the assimilative organs. Second, Glycosuria. We have now greater changes in the assimilative organs, but their perverted action has not yet become habitual. Sugar appears and disappears from time to time, owing to causes partly dietetic. Third, True Diabetes Mellitus. Now the perverted action of the assimilative organs has become habitual, and sugar in varying amount is constantly found in the urine.

These three conditions can be clearly diagnosed.

The first two, pseudo-glycosuria and glycosuria, as a rule, yield to dietetic and hygienic treatment. I place but little confidence in drugs in the treatment of this disease. The third, true diabetes mellitus, if recognized in the early stage, when the amount of sugar is small, though persistent, may yield to treatment ; but if it does not come under observation until the advanced stage has been reached, must, as I have before said, be regarded, though amenable to treatment, as incurable.

254 West Forty-second Street.

A Dress for Physicians.—Some individual has suggested that physicians adopt a peculiar style of dress in order to distinguish them from the vulgar herd. We doubt whether a peaked cap with bells would render the originator of this scheme any more conspicuous among his fellow-men.

ANTIPYRIN AS AN ANALGESIAC.

By P. R. Egan, M.D.,
Assistant Surgeon, United States Army.

Now that antipyrin is taking its place in medicine as an efficient analgesiac, it might be of interest to your readers to record some short notes of nervous cases treated before and since its introduction.

Case I.—Miss M—— (1882). Neuralgia left supra-orbital. Headache said to follow an injury over left eye where a piece of glass remained in the wound for some time. Always brought on by excitement and worry. Photophobia during attacks. Vomiting gives no relief. Caffein and ungt. veratria no relief. Bromides, iron, and arsenic, no relief. Morphia produces very distressing after-effects.

Case II.—Mrs. G—— (1882). First had headache from living in a low malarious region. It is distinctly periodic—" comes always on a Friday." Has been treated by various doctors with all sorts of remedies. Quinine faithfully tried and found wanting. Strychnine, iron, and arsenic, no relief. Objects to morphia.

Case III.—Mrs. S—— (1883). Hemicrania ; marked hereditary migraine, anæmic in character. Follows indigestion. Relief from vomiting. Treated for indigestion, but never found any medicine to produce improvement or give relief.

Case IV.—Mr. M—— (1883). Inveterate cigarette smoker. Suffers from pseudo-angina. Has attacks of sick headache, but never vomits. During attacks has difficulty in reading, and can only see half the things looked at. Cannot remember names when he hears them, and continually uses wrong words. No relief from medicines. Bromides, caffein, iron, and arsenic.

Case V.—Mrs. I—— (1884). Right supra-orbital neuralgia. Comes on periodically from exposure to cold. Relieved by hypodermic of morphia, and by H. C. Wood's mixture, but declines to continue their use. No other medicine found availing.

The following classes of cases were treated by antipyrin :

Class I.—Case of sciatica, right thigh, relieved. Only half (grs. x.) the medicine intended (grs. xx.) was taken.

Class II.—Three cases of diffuse neuralgia of fifth nerve, with swollen face from exposure to cold, were cured inside one hour by doses of fifteen grains.

Class III.—Four cases of migraine were relieved by fifteen-grain doses. "Acted like magic," "Never had anything so good," were the statements of grateful patients.

Class IV.—Three cases of dysmenorrhœa with severe pain prior to the flow, relieved by two doses of fifteen grains each.

Class V.—Case of pseudo-angina pectoris, relieved by fifteen grains in one-half hour.

Class VI.—Case of intercostal neuralgia cured. No return in eight months.

Class VII.—Case of earache, with marked improvement of hearing during attack, but no discoverable inflammation. Occurred once before. Relieved by two doses of fifteen grains each. No return in over six months.

Class VIII.—Case of chronic muscular rheumatism, relieved by one dose of fifteen grains.

Class IX.—Case of gastralgia. No dyspepsia and no relation to taking of food. Cured by two doses of fifteen grains each. No return in ten months.

Class X.—Case of dull headache over brow, relieved by grs. x., but returned next day. Was not suited to this treatment but to mineral water, pepsine, and acids.

Remarks.—Unfortunately antipyrin, like other analgesiacs when frequently used, tends to lose its effects unless increased in quantity. In one case under my care its effect decreased markedly, and in another reported to me it wholly disappeared. No evil consequences followed its administration, save in the case of a child, four years old, where two doses of four grains each, given an hour apart, produced vomiting lasting eight hours.

In all the cases reported prior to 1885 antipyrin would have saved my patients much mental worry, and often the keenest physical suffering.

Professor H. C. Wood's mixture I became acquainted with in 1884, and find it equally effective, but its composition is often objected to, as it was in Case V.

Hammond's large doses and Little's (Dublin) mixture I have had no experience with.

Clinical Department.

PENGHAWAR DJAMBI, NOT A NEW HÆMOSTATIC.

By K. A. NORDERLING, M.D.,
ROCKFORD, ILL.

In The Medical Record of July 21, 1888, penghawar djambi is mentioned as a new hæmostatic, which, however, is not the fact. The botanical name of the plant from which the drug is derived, is cibotium cumingii, and it is indigenous on Sumatra in the province Djambi, hence the name. It is a tree-like fern, and the parts employed are the fine hairs that surround the base of the leaves and stem.

The drug has been used by the natives since times immemorial as a hæmostatic.

Fifty years ago Kool, of Amsterdam, wrote about its hæmostatic property; by him it was confounded with the agnus scythicus, known in the sixteenth and seventeenth centuries also under the name of trutel tartareus, which was then thought to be a link between the animal and vegetable kingdoms, a vegetable lamb. This agnus scythicus was, however, derived from another country and another fern.

Penghawar is mentioned in Miguel's "Analectica Botanica Indica," No. 34. It was introduced in the Pharmacopœia Neerlandica, 1851, as a hæmostaticum. Dr. Vinke, of St. Petersburg, experimented with the drug in 1854, and his experiments are given below: Two beakers, each holding about four cubic inches, were filled with recently-drawn blood from a plethoric person. The beakers were placed in water, which was kept at a temperature of 100 F. during the experiment. Five grains of penghawar was put in one of the beakers, and after the expiration of three minutes the blood was transformed into so firm a coagulum that it did not fall out when the vessel was turned upside down.

In the other beaker the blood, even after twenty minutes, remained mostly liquid. Ten minutes thereafter, under a room temperature of 65° F., the coagulum with the penghawar was so firm that it with difficulty could be torn asunder with the fingers, and the volume to the surrounding serum was as two to one. The coagulum in the beaker without the penghawar was viscid and easily torn, and was floating in a quantity of liquor sanguinis which was three times greater in volume than the coagulum. Similar experiments with blood from persons afflicted with different diseases gave the same result.

The blood always coagulated with penghawar within four minutes, but the spontaneous coagulation did not occur until after the course of twenty minutes or even longer. The larger the quantity of penghawar that was used the less serum was separated, and the sooner was a firm coagulum formed. In one instance seven grains of penghawar in two cubic inches of blood produced a firm coagulum in two minutes, from which no serum was separated. A like quantity of the same blood but without the drug commenced first to coagulate around the sides of the vessel after twenty-five minutes, and could then easily be poured out into another vessel. Similar experiments were tried with penghawar after having been macerated in sulphuric ether, caustic potash, or dilute hydrochloric acid, and then boiled in water and perfectly dried in the sun before experimenting; the results were the same.

On the presumption that the hæmostatic power of penghawar was derived from its physiological quality, comparative experiments were made with agaricus chirurgorum, lycopendron bovista, and spongia marina. The agaric and the bovista were reduced to threads, and the sponge cut up in small pieces. In every experiment the blood was taken from the same person, and immediately after venesection divided up in four vessels that had a capacity of four cubic inches. These were placed in water of 100° F. In the first glass was put five grains of agaric, in the second, five grains of bovista, in the third, five grains of spongia, and in the fourth, the same amount of penghawar.

At a room temperature of 75° F. the following results were obtained. A firm coagulum was formed of:

	Penghawar Minutes.	Agaric. Minutes	Spongia. Minutes.	Bovista. Minutes.
In 1st experiment in	3	11	8	7.5
2d " "	2.5	12	10	8
3d " "	2	10.5	9	6.5
4th " "	1.45	10	7	6
An average of	2	10.52	8.30	7

The result not only shows the superiority of penghawar but also explains its *modus operandi*.

Agaric and sponge consist of twisted threads which are not hollow. The blood, therefore, only penetrates the meshes of their tissue (not the interior of the threads) and congeals there a little sooner than when left alone in the air. At the end of six minutes fluid blood could be squeezed out from the agaric and the sponge. The hairs of the penghawar that have been used to form a coagulum will swell out five times their thickness, and assume an almost cylindrical shape without changing color or transparency.

The coagulating property of penghawar djambi depends, therefore, upon its quality of depriving the blood of its serum, which is absorbed into the fine capilli of the drug.

The drug was used considerably thirty years ago, but has fallen into oblivion (which is the fate of so many good or bad drugs). As it has been very hard to obtain it has not been used as much as it deserves.

OPERATION FOR ANCHYLOSIS OF THE KNEE-JOINT, RESULTING IN GANGRENE—AMPUTATION AT THE THIGH—RECOVERY.

By A. L. STAVELY, M.D.,
READING, PA.

About sixteen months ago Mrs. Sarah H—— noticed for the first time a sharp pain in her left knee, which became so intense that she could hardly walk. The knee was much swollen, and the leg became so much flexed that the big toe would not touch the floor by fully four inches. On September 18, 1887, she went to the Jefferson Hospital, where her leg was placed on and bound fast to a long posterior splint. Then gradual extension by means of weights was resorted to, and after ten weeks her leg became considerably straightened. That condition remained only for a week or so, at the end of which time the leg became flexed again and the pain increased.

The patient can give no adequate cause for the anchylosis, though her sister maintains that she had "milk leg" at one time. On August 6th she was persuaded to submit to an operation, and came to the Reading Hospital for that purpose. About 4 P.M. the same day she was anæsthetized, the adhesions were broken up and the leg was bound down to a long posterior splint. She was then removed to the ward and a hypodermic of morphia, one-quarter grain, was given. The pain from the operation was very great and it was several hours before she became quiet. On the morning of August 7th there was a visible cyanosis of the nails of the left foot and some impairment of sensation also. Although the bandages were not tightly enough applied to interfere with the circulation, they were removed and the leg left unencumbered. Stimulation by alcohol, friction, and heat was resorted to. On the 9th there was decided impairment of sensation, and on the sole of the foot near the toes there was a small white spot where the epidermis had become loosened from the corium beneath, and around it was a bluish areola. On the 10th and 11th the foot became uniformly purple, blebs formed beneath the epidermis, and the leg up to the knee became intensely swollen, hot, and extensively infiltrated with serum, and at the same time was very painful. On the evening of August 17th her temperature was $104\frac{2}{5}$° F.; on the morning of the 19th it was $102\frac{3}{5}$° F. On the same morning there was a consultation, and it was decided to remove the gangrenous part, the amputation to be at a short distance above the knee. The operation was performed about noon and consisted of the modified circular of Dr. D. Hayes Agnew. There was a dark-looking mass of muscle posteriorly which looked suspicious, and as it appeared to extend upward a considerable distance no attempt was made to remove it. The operation was performed antiseptically and there was perfect coaptation of the parts. Five or six strands of catgut were put in for drainage, and the wound was dressed antiseptically with iodoform. At 7 P.M. the same evening the temperature had fallen to $99\frac{1}{5}$° F. and at no time after the operation did it go above 101° F. The dressings were removed on the sixth day; and there was union by first intention along the whole length of the wound, and the catgut had become absorbed. On the following day the stitches were removed and the patient was allowed to wheel herself around in a wheel-chair. The patient was discharged well, thirteen days after the operation.

WHISKEY NOT AN ANTIDOTE TO RATTLESNAKE POISON.

Dr. A. T. Hudson, of Stockton, Cal., writes: "Having often seen the statement made in the public press, and sometimes in medical journals, that whiskey and ammonia were the acknowledged antidotes to rattlesnake bite, I feel it a duty to administer a corrective to the above fallacious teaching. About thirty years ago Professor Weir Mitchell, of Philadelphia, spent over two years in carefully experimenting with the virus of snake poisons. Taking a few drops of the pure virus from the sack of the snake, he mixed it consecutively with alcohol, ammonia, iodine, bromine, mercury and other reputed antidotes, then injected the solution of each into birds, rabbits, dogs, goats, and other animals—when he found that the poison was not altered in its power, but would produce its specific toxic effect just the same as when it was undiluted. He found also that the virus was fatal only to a certain extent, that is, if it took half a drop to kill an animal of thirty pounds weight it would require one to two drops to kill one of sixty to eighty pounds. Its action is immediate, and it kills only when the animal is too small and weak in resistive vitality. It is rare that an adult person dies from the bite of a rattlesnake. The virus of the cobra is more intense and fatal. Several years ago a prominent minister in Philadelphia died from the bite of a young cobra. As a given quantity of the rattlesnake virus is necessary to overcome a certain amount of physical force, it is seldom that such quantity is ever deposited by the snake bite upon an adult person. If a large snake should bite a goat of fifty pounds weight, and soon after bite two children of about the same weight, the goat might die but the children would not, for the reason that the goat would receive the largest amount of the virus, when there would be but little left to poison the children. In such a case whiskey being used on the children, their recovery would be attributed to the whiskey, so the friends and neighbors would think they have positive proof of a sure antidote in whiskey. Here is the fallacy which science alone can demonstrate. If, when whiskey is mixed with the poison directly, it is no antidote, how can it become so when taken into the system remotely, the whiskey in the stomach and the poison in the goat? Physiologically whiskey is antidotal so far as it will sustain the flagging powers during the time the poison is being eliminated by the excretory organs. In the light of the above scientific demonstrations, how a doctor can gravely or frantically proceed to treat a rattlesnake bite 'by injecting around the wound permanganate of potass, or any supposed antidotes, or order a chicken split open and applied to the wound, or the anus of the chicken applied over the wound, using a number of different fowls for the purpose,' is a problem hard to understand in this age of reason."

CASE OF SUPERNUMERARY NIPPLE ASSOCIATED WITH MATERNAL IMPRESSION.

Dr. Arthur H. Coe, of Ann Arbor, Mich., reports the following: "Mrs. O——, aged thirty-two, two children, the elder aged twelve years, has always enjoyed good health. The left breast presented two nipples, the smaller, or supernumerary one, being about two inches below the normal nipple. It was correctly proportioned and surrounded by a faint areola. The patient stated that during lactation the secretion flowed freely from the lower nipple, requiring the application of a bandage. The possibility of the supposed nipple being a fistulous opening with everted edges resulting from an old abscess, was considered, but a careful examination and a statement by the patient, to the effect that the two nipples had been present as long as she could remember, seem to be conclusive evidence against that possibility. An interesting point in the case centres in the possibility of the malformation being due to a so-called 'maternal impression.' Upon inquiry the patient stated that her mother, when about two months advanced in pregnancy, was much startled on one occasion by a young kitten, which jumped upon her breast (the left) and seized the skin just below the nipple. She was much prostrated by the occurrence, which made a deep impression on her mind. The subsequent birth of the child with the peculiar malformation, would seem to indicate some dependence thereon."

COCAINE USED IN OPERATING FOR SINGLE HARELIP.

Dr. Frank P. Hudnut, of Brooklyn, reports the following: "Boy aged nine years, of healthy parents, had a well-marked case of harelip on the right side, with cleft palate. He was unable to hold water in his mouth after the glass had been removed from the lips. After fastening two clamps on the lip to cut off as much of the circulation as possible, I injected, in four places along the lines for incision, fifteen minims of a four per cent. solution of cocaine. After waiting about three minutes I proceeded with the operation. The child never cried or appeared to suffer until I was introducing the last two stitches. The operation was a complete success in every way. The stitches were removed on the third day. I report this case, as it is the first one (to my knowledge) where cocaine has been used in this operation."

DEXTROCARDIA.

Dr. James F. Michel, of Jamesville, writes: "In The Medical Record of September 8, 1888, I read an account of a case of dextrocardia. Some two years ago I met one of these rare cases, which may be of interest. The patient had been informed that his heart was not where it ought to be, and wished me to examine him. I had him strip to the waist and examined him closely and thoroughly. The following is a copy of notes taken at the time: A. L——, negro, aged twenty-two years; unmarried; occupation, barber; height five feet seven and one-half inches; weight, one hundred and fifty-five pounds; erect, well-built, muscular; has always been healthy, and his heart never troubled him at all. The heart is exactly reversed as to side of body—apex just below fifth rib, and three and one-eighth inches to the right of the mesial line. Base directed upward, backward, and to left. Area of heart dulness (right side, of course) about normal, merging below into line dulness; no dulness on the left side. The heart sounds are normal. Pulse normal, full and strong. Respiration regular. So far as I could determine on careful examination, all the other viscera were in their normal position. I made an appointment with the young man to re-examine him in presence of some professional friends, but he failed to keep the engagement, and I have never seen him since, so I can only send you my own unsupported statement and diagnosis."

Progress of Medical Science.

Alaninate of Mercury; A New Antisyphilitic.—Schmiedeberg's suggestion that combinations of mercuric oxide with certain amidic acids of the fatty series (acetamidine glycocollamine, asparagine) should act well in the treatment of syphilis, and the fact that these preparations have the advantage of being very soluble and easily absorbed, induced Dr. R. De Luca, assistant in the clinic of Professor Ferrari in the University of Catania, to make some experiments with mercuric alanine in the treatment of syphilis, and these he has now published. Preliminary experiments on animals (rabbits, Guinea-pigs, and dogs) showed that the drug was not very poisonous.

The alaninate of mercury used was prepared in the following manner: One part of alanine was dissolved in twenty parts of distilled water, which was then gradually raised to the boiling point; while the liquid was boiling it was poured over a small quantity of mercuric oxide (HgO) until it was all dissolved. Then the liquid was filtered and evaporated, and the residue crystallized, and a whitish substance, mercuric alanine, was obtained, which under the microscope showed the characteristic needle-shaped crystals grouped in crosses and tufts. When thus prepared alaninate of mercury is soluble in three volumes of cold distilled water; this aqueous solution is perfectly colorless, clear, is changed neither by exposure to the air nor to light, and will keep indefinitely. In dilute solution it will not coagulate albumen; in concentrated solution its coagulating action is limited to its causing a cloudiness of that part of the liquid with which it comes immediately in contact. In other respects it has the general properties of other salts of mercury.

On his patients De Luca used the drug in three different solutions of 4, 8, and 10 milligrammes to 1 c.cm. of distilled water (gr. 1-16, 1-8, and 1-6, to 16 m.), both for internal use and for injections, subcutaneous or intermuscular. The drug was used by injection in twenty cases; nineteen cured and one improved. The daily quantity used on each patient (all adults) was from five to ten milligrammes. The average number of days of treatment for each patient was 37.05; average number of injections to each patient, 27.7; average age of patients, 23.2 years. In the case that improved but was not cured, the patient stopped treatment. All the cases were those of secondary syphilitic lesions. Each patient received an average quantity of 228 milligrammes (gr. 3.5). Only three times did suppuration occur at the site of injection. As regards the duration of treatment, then, it is seen that mercuric alanine has some advantage over the bichloride; as to the quantity to be used it has a decided advantage, the quantities being as 22.8 to 42. With regard to the efficacy of the alaninate, in twelve cases (out of the twenty) that could be seen to ascertain if any recurrence had taken place, there was only one case of recurrence, in a case of syphilitic papule of the larynx. From this it seems that the alaninate gives more permanent results than other mercurial preparations. Further, in not a single case in which the drug was used by injection was there any stomatitis or other unpleasant effect produced. From a tabulated statement of twenty cases treated by the internal use of the drug, it is seen that for the cure of ten adults with secondary syphilitic lesions, there was an average of 45.4 days and 641 milligrammes to each patient. Of ten children treated one died on the third day. For the cure of the remaining nine, of an average age of 7.4 months, with hereditary or acquired syphilis, each required an average of 54.6 days, and 159 milligrammes of the drug. Of the nine cured six were seen in from eight to nine months after treatment was stopped, and there was no recurrence in any one of them. There was not a case of stomatitis, and only one case of intolerance of the drug, which was completely controlled by the administration of cocaine. Regarding the internal use of the alaninate, then, it is not to be preferred to the tannate or the phenate of mercury in the opinion of De Luca, but the easy tolerance of the drug, and the excellent manner in which it acts on syphilis in infants, make it an important addition to the list of anti-syphilitics. The child that died was only two months old, and was in a desperate condition when it came under treatment. De Luca claims that the decidedly calmative effect of the drug gives especially happy results in children. The author thinks that the drug is worthy of confidence, and that time may prove that it will give good results in the late manifestations of syphilis.—*Medical Journal and Examiner.*

Phosphate of Copper in Tuberculosis.—Dr. Luton, of Rheims, says that he is convinced that tuberculosis may be cured by phosphate of copper in a nascent state. He recommends the following formulæ:

1. Pills of the aceto-phosphate of copper.

℞. Neutral cupric acetate........... grs. iij.
Crystallized sodic phosphate....... ʒ ss.
Div. in pilulas No. xx. Ten such pills constitute a daily dosage to commence with.

2. Potion of aceto-phosphate of copper.

℞. Neutral cupric acetate........... gr. jss.
Crystallized sodium phosphate.... grs. xv.
Mucilaginous potion............. ℥ viij.
M. The dose is a tablespoonful repeated p. r. n.

3. Hypodermic solution of phosphate of copper.

℞. Cupric phosphate (freshly precipitated). gr. $\frac{1}{6}$
Glycerin, pure,
Distilled water .... āā ♏ xl.
Mix at the moment of using.

Luton thinks that the initial dose should not be more than one and one-half grain daily of the copper salt, and he adds that the specific medication should be supplemented by a special tonic to confirm the cure and prevent relapses. He suggests the following tonic wine, which he calls phosphated wine of walnut:

℞. Extract of walnut................. ℥ j.
Phosphate of sodium............... ℥ ss.
Malaga wine....................... O ij.
M. Sig.—A tablespoonful after meals.

Effects of Acute and Chronic Cocaine Poisoning.—Dr. Zanchevski, of St. Petersburg, has published some observations on the pathological changes found in the bodies of animals poisoned by cocaine. The experiments were made in two series. In the first series the animals (dogs) were given hypodermically a single lethal dose of cocaine—viz., 3 centigrammes per kilogramme of the weight. In the second series of dogs chronic poisoning was induced by the subcutaneous injection of a much smaller quantity—about the fifth part of the lethal dose was given every day for six days. A day was then missed, and during the next six days an increased dose given. Every seventh day was missed, and the dose gradually increased. Thus, dog No. 6, weighing 5650 grammes, was experimented on for seventy-three days. During each of the first six days 3 ctgr. were given; during the next six 4 ctgr. For ten days 5 ctgr. were given, for thirteen days 6 ctgr., for eleven days 7 ctgr., and for the last eleven days 8 ctgr. The total quantity given was 3.35 grammes. One day in the week was always missed. At the beginning the immediate effect of the cocaine was seen in increased frequency of the cardiac beats and of the respiration, which, however, did not last more than a quarter of an hour. Afterward great weakness of the legs came on, the animal remaining in a sitting posture and swaying its head to and fro. The pupils were dilated and sensation intact. In three hours the normal condition returned. When larger doses were given the disturbance was greater, the animal commencing to try to run about and the subsequent weakness lasting for a longer period. The general results obtained by observation of the animals during life and by post mortem examination of the bodies showed that in acute poisoning the mode of death was asphyxia. In chronic cases without asphyxia there was a marked hyperæmic condition of the central nervous system, which presented a contrast to the state of the rest of the organs, which were anæmic. Albuminoid degeneration was especially marked in the ganglionic cells of the spinal cord and the nerve cells of the heart ganglia; it was present also, but in a less marked degree, in the muscular fibres of the heart, in the ganglionic cells of the medulla oblongata, and in the hepatic cells. In these last there was found an accumulation of glycogen. In chronic poisoning the degenerative processes were found to have advanced further in the cells of the spinal cord and medulla, minute cavities, atrophy, and hyaline degeneration being noted. In the heart there was fatty degeneration of the muscular tissue; in its nerve ganglia there were fatty degeneration, minute cavities, and simple atrophy; and in the liver atrophy of the hepatic cells was present. The vascular system was most affected in the spinal cord, there being cellular proliferation and hyaline degeneration of the coats. In the heart and liver an atrophic condition of the tissues was found, also a swelling of the endothelium of the capillaries of the cardiac ganglia.—*The Lancet.*

Spontaneous Expulsion of a Vesical Tumor after Perineal Incision.—Bruhl relates a case in which he opened the bladder by the usual perineal incision, introduced his finger into the bladder after dilating the prostate, and found a hard incrusted mass lying behind the neck of the bladder. The mass at once slipped out of his grasp, and he could not again find it. The following day, after some considerable amount of pain, the patient expelled a tumor covered with calculous material, about two inches in length and two in breadth. The wound was completely healed in fourteen days.—*Centralblatt für Chirurgie.*

The Sightseer's Headache.—Of the lighter penalties which pleasure entails, none probably is more widely known and felt or more persistently endured than the sightseer's headache. It is nature's tax levied on the comfort of that great body of busy idlers to which we all at some time or other belong. (*The Lancet.*) It is endemic among the frequenters of museums, picture galleries, and exhibitions, varying somewhat perhaps in different cases in its precise causation, but associated always in a manner significant of its origin with the habits of the observant loiterer. The circumstances in which it arises afford the most reliable clue to its true character. Among these, temperature, atmosphere, and strain both of body and mind, though commonly combined, play their several parts in varying degrees of activity. The influence of a warm and close atmosphere as a cause of headache is too well known to require more than a passing notice. The torpid congestion of tissue which it tends to induce, and from which the brain is not exempted, is familiar to most of us as a morbid process too often illustrated in our painful experience. It contributes its proportion, doubtless, toward that total of malaise which affects the visitor to a crowded picture-gallery or assembly room, and culminates in the localized ache which renders the slightest mental effort a weariness. The very general prevalence of this variety of headache, however, and its independence in many instances of any vitiation of atmosphere, teach us to look for its explanation in other causes. The effort of mind implied in long-continued observation, even though this does not involve the strain of study, has probably an appreciable, though a secondary, influence. Fatigue certainly has an important share in its production; but it is with most persons rather fatigue of muscle than of brain. The maintenance of the upright posture during several hours of languid locomotion, the varied and frequent movements of the head commonly in an upward direction, and the similar and equal restlessness of eyes whose focus of vision shifts at every turn as a new object presents itself, form a combined series of forces more powerful in this respect than the sunlight and frequent changes of mental interest and attention by which they are accompanied. The muscular strain implied in these movements is necessarily very considerable. It affects more or less every member of the body, but the distant localization of the resulting ache has probably much to do with the unusual activity of the cervical extensor and rotator muscles and of the muscles which move the eyeball. Whatever the minor influences at work, therefore, there can be little doubt that mere fatigue is primarily accountable for this most general form of headache, and that rest and nourishment are most reliable antidotes. The utility of stimulants for this purpose is necessarily temporary and deceptive. One improvement on existing arrangements ought to be of real assistance to the suffering sightseer if more generally introduced by responsible authorities. The comparative scarcity of seats in many places of amusement has often been noticed. It would be much to the public advantage if this want were supplied. For the attendants at exhibition stalls a chair for occasional use is an absolute necessity.

Disease of Adrenals without Bronzing.—At a late meeting of the London Pathological Society Dr. Collier showed the right suprarenal capsule of a woman, aged thirty-six, who had been ill for nine months with exhaustion and vomiting. She was anæmic, but well nourished, and not bronzed in any part; the pulse was extremely weak. While in the Radcliffe Infirmary, the most characteristic feature was the extremely languid condition in which she lay in bed. The patient died suddenly. Both suprarenal capsules were enlarged; the right capsule was entirely caseous, the left was reduced to a small sac containing cheesy material. The history showed that the suprarenal capsules had been diseased for at least nine or ten months, which rendered the absence of pigmentation the more remarkable.

The Incompatibility of Antiseptics.—Dr. Boxall calls attention to a very important point in connection with the employment of mixed antiseptics. He has ascertained that mixtures of corrosive sublimate and iodine, iodine with carbolic acid, and carbolic acid and olive oil, produce chemical changes which materially affect the properties of the original constituents. He found, moreover, that soap and glycerine are, as a rule, bad vehicles for antiseptics. Perchloride of mercury, iodine, salicylic acid, and permanganate of potassium are changed or precipitated by admixture with soap. It is evident, therefore, that some little discrimination is necessary before we employ other than simple solutions of the principal antiseptics.—*Medical Press.*

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, October 20, 1888.

THE ANGLO-GERMAN CONTROVERSY.

It is deeply to be regretted that the medical profession is again subjected to the evils of a bitter controversy between eminent representatives of the science. Beset as the divine art of medicine is on every hand by empiricism, and struggling as it is into the light of a higher intelligence, it is lamentable for its votaries to witness the blows against its dignity from those who have risen to just eminence in its ranks, and who should, by virtue of their distinction, be the conservators of all its best interests. Silence, even under great provocation, is always welcomed and appreciated by the profession at large, when by breaking that silence harm is done the whole body of medical men by lowering the high standard of professional dignity; and it is a very serious question how far a physician may go in defence of himself at the expense of the profession and its membership. Still, heated professional controversies are not so infrequent as to be remarkable when one does occur. In theology, law, medicine, and politics, where discussions are not "cribbed, cabined, and confined" by the rules of an exact science, and where opinion frequently takes the place of observed phenomena from which deductions are made and conclusions drawn, it is not uncommon to see acerbity in debate and temper shown by disputants. But for intensity of feeling and bitterness of language, no professional dispute of recent years can compare with that now raging between the British and German physicians who were in attendance upon the late Emperor Frederick. When we think of the exalted rank of the patient and the eminence to which the warring surgeons have attained—their wide reputation for learning and professional skill—it becomes almost incredible that such regrettable and embittered differences should exist as are disclosed in the indictment and answer of Sir Morell Mackenzie.

The highest political considerations, national pride, and personal ambitions, without question, have entered largely into the dispute and contributed to its passionateness and intensity, and have fanned into a flame what may have been at first an honest difference of opinion of every-day occurrence between professional men. But whatever may have been the rivalries, jealousies, and ambitions which led to the quarrel, the existence of the controversy itself cannot be ignored.

The accusation and the answer of the accused are before the public for decision and a verdict. And as it looks now like a Reply and a Rejoinder will soon follow before the pleadings are made up, we will confine ourselves to a brief examination of Sir Morell's brochure,[1] issued in London this week, advance sheets of which are before us.

In May, 1887, Mackenzie was summoned to Berlin to see the Kronprinz. Upon arrival he was requested by the patient to examine his throat. He suggested instead a conference with the other doctors in attendance. They were Professors Gerhardt, von Bergmann, and Tobold; Dr. von Lauer, Emperor William's physician; Dr. Wegner, Crown Prince Frederick's physician, and Dr. Schrader, a German army physician. The consultation resulted in the statement that there was a small growth on the left vocal chord, about the size of a split pea, which Dr. Gerhardt had attempted to destroy by galvano-cautery. An examination by Mackenzie followed, confirming the presence of the growth on the chord. Except for loss of voice the throat gave no trouble to the patient, no pain, no dyspnœa, no hinderance to deglutition, and to every outward appearance the Prince was "a model of stalwart health, far stronger than the average even of strong men."

After the examination the question of diagnosis came up. The three German professors pronounced the disease cancerous, and recommended external partial laryngeal excision. Mackenzie took the ground that "there was nothing characteristic in the appearance of the growth, and that it was quite impossible to give a definite opinion of its nature without a more searching examination." He proposed cutting off a small piece of the tumor with the forceps, and submitting it to Professor Virchow for microscopic examination, and to allow Virchow's report to govern the question of excision. This was agreed to, and the minor operation fell to Mackenzie (as he claims) because of the incapacity of the other gentlemen to perform this particular *manœuvre.*

It was at this first consultation that the seeds of dissension and hostility were shown, and which steadily grew till the death of the patient temporarily put an end to the quarrel, but which was reopened in public with increased bitterness as soon as the doors of the tomb closed upon the illustrious dead.

It is not the province of this review to express any but a modified opinion as to the merits of the various questions involved in the dispute. Before any definite decision can be formed, the Reply of the Germans and the Rejoinder of Mackenzie will be essential to any fair and complete estimate of the evidence and facts in the controversy. However, there are many things in the statement under review which we may touch upon without prejudice to either side.

In this instance, that Mackenzie is fully justified in making an elaborate defence we believe no one acquainted with the facts will dispute. He has been assailed, from the day following his first arrival in Berlin, with all the weapons of political and professional warfare; his assailants have not only used the German medical journals, but have had full use of the secular and Imperial press as well. He was practically alone in a hostile camp, with the prejudices and passions of the people inflamed against him on account of nationality, encouraged no doubt by the powerful influences of the Court. His position was one of the greatest difficulty, not only because of the grave responsibility of the case itself, but what may be called the "external, political, professional, and international complications." This hostility culminated at last in accusations, from the Berlin Imperial Press, equivalent to a charge of malpraxis, and we must agree with Mackenzie, that one must be more—or less—than man to bear such allegations in silence and without response.

---

[1] The Fatal Illness of Frederick the Noble. By Sir Morell Mackenzie. London: Sampson Low & Co.

The answer made, however, goes farther, and passes into such an acrimonious criticism of Sir Morell's German colleagues as to amaze the reader, and create hesitancy in accepting many of the allegations without first hearing the other side. The book presents such a narrative of intrigue, hypocrisy, theatrical pretence, jealousy, envy, suffering, and professional incompetency, as to be discreditable to humanity; and if but a portion is substantiated, it will show the immeasurable advance of English and American practice, not only in medical and surgical skill, but also in those humanities and amenities of life which have done so much to elevate and ennoble the profession in the popular mind.

Here we have presented to us the spectacle of an eminent German surgeon burning the vocal cord with the galvano cautery, daily, for twelve consecutive days. We see professional gentlemen who first tell the world the private details of professional consultations, and shock the patient and his family with undetermined suspicions of a horrible disease, and afterward lecturing in public, while the patient yet survives, upon a newer theory of the disease—a theory which, while it could not add anything to the terrors that cancer conveys to the mind of a patient, yet did add the shame and humiliation of an allegation that the trouble was due to venereal contagion. We find an accusation that a consulting surgeon deliberately mutilates his victim to bear out a false theory of diagnosis; spies surround the surgeon in charge and follow him from place to place, and incompetent pretenders are permitted to torture the patient in order to support their own claims to importance and learning; truculence takes the place of independence of thought and integrity of opinion, and a most extraordinary and unaccountable butchery, by an over-stimulated or excited surgeon, closes the mournful scene. Taken all in all, it is difficult for the imagination to picture a more revolting play of the baser passions than we find depicted in and between the lines of Mackenzie's narrative. It is a recitation in any point of view to be regretted and deplored, and we hope, for the good name of the German faculty, who have contributed so greatly to modern medical learning and research, that the gravity of the charges brought by Sir Morell may be modified by further facts and explanations.

It may be said, however, to the credit of medicine, that the cause and origin of much that was discreditable in the conduct of the case was extra-medical, and due to the court intrigues at Berlin.

This much in a general way; and now, upon the main point at issue a few words:

The fundamental difference between Sir Morell and the German physicians appeared at the first consultation. The Germans believed the disease to be malignant, and the result proved they were right; for, however much we might condemn the practice of galvano-cautery as used by Professor Gerhardt, yet we cannot agree with Mackenzie that this led to the subsequent development of the disease. But, in the light of American conservative surgery, we do endorse Mackenzie's procedure in first seeking Virchow's report as to the microscopical appearance of the growth before accepting the theory of cancer, especially when that acceptance was the first step to an operation of the gravest and most doubtful import. Virchow's report justified Mackenzie's position, and after the reception of the report, which was negative in its conclusions as to cancerous conditions, even they who advocated laryngeal excision could not consistently demand it in the face of Virchow's great pathological authority.

To illustrate: Suppose excision had been performed at this time, and that the patient had succumbed, either under the knife or a few days or weeks afterward, as is commonly the case. Suppose, then, the report of Virchow upon the excised portion had been the same as he did give, showing no cancerous condition present. What would then have been the professional and lay verdict against the physicians responsible for the seemingly needless and hazardous performance? Inexcusable and unpardonable.

This difference at the beginning was the fundamental one, and from it sprang all the subsequent disputes and controversies. What the result might have been if excision had been resorted to can only be conjectured. If the operation were to be performed at all, there is no question that it was better early than too late, and in this the German view seems right; but in the light of all the facts, the subsequent history of the case, and the tables of similar cases, American opinion, we think, will incline to the belief that excision would not have prolonged life much more than the course pursued extended it, and that, in addition to this belief, the general treatment which was followed avoided the grave dangers and accidents of the major operation. While American surgery has been on many occasions both brilliant and original, yet we feel that its general tone is one of conservativeness and great caution, because, no doubt, of the great practical character of our people; and on the basis of conservative surgery American opinion, we think, will be with Mackenzie upon this most important feature of the case. As to the controversies which were incessant in conducting the case on this general line of treatment we do not care to speak until both sides are fully before the public, and possibly not then, as they are subservient to the central difference, and are more of personal than professional interest. Yet, notwithstanding all that has been said and done and written about this celebrated case, much of which was calculated to lower the popular esteem of the efficiency of medical treatment, we cannot rise from a perusal of this book without a profound sense of the resources and skill of modern medicine and surgery, of which the Crown Prince had the benefit, and by and through which his life was prolonged to the ascent of the imperial throne and the assumption of his inherited rights and dignities. We cannot close this brief review without a word in eulogy of the great soul that bore up so manfully under conditions that would shake the firmest resolution and the stoutest heart. Throughout the terrible ordeal the illustrious patient bore himself with a heroism that will adorn the page of history, and always command the respect and love of his fellow-men in every walk in life.

ACUTE LOBAR PNEUMONIA.

In another column Dr. Gouverneur M. Smith calls attention to the seasons of the year in which pneumonia is most rife among us; to its increasing death-rate; dwells specially on one important point in its management; and gives a hospital reminiscence illustrating a former popular method of its treatment.

Pneumonia is a dreaded disease, more dreaded than formerly on account of its augmented mortality. The cause of such increased mortality is, in a measure, veiled in mystery. It is essential for the medical profession to carefully garner all known truths regarding the disease, and to utilize them, while, at the same time, endeavoring to unfold its unsolved problems.

Of late years large doses of quinine and the use of antipyretics have been extensively employed in the treatment of the disease, but their services have not been satisfactory. Since the clinical thermometer has come into general use, special heed has been given to the temperature of the patient; before that time, perhaps more attention was paid to the pulse, skin, secretions, etc., and appropriate remedies exhibited to mitigate conditions, without reliance on a mere Fahrenheit scale. However this may be, it is of great importance for physicians to study the enervating influences which are checking medical supremacy over the disorder, and to continue the investigation until the usurped power of a disease has substantially yielded to the higher authority of therapeutics.

DEGLUTINATION OF THE CARDIAC MUSCLE-CELLS.

In many cases of sudden death said to be occasioned by heart disease, the diagnosis is assumed rather than proved, the post-mortem changes offering no anatomical basis for such an opinion. There may be some degree of softness of the muscles, but it is not pronounced, and a diagnosis of cardiac degeneration or paralysis is made for want of a better one.

Dr. Klein, of Warsaw (*Gazeta Lekarska*, No. 18, 1888), has recently made a study of these cases, and has found a possible explanation, for some of them at least, in a change in the grouping of the cells of the cardiac muscle. As has been shown by Weismann, the muscle-cells in the mammalian heart are quadrangular in shape and more or less branched, and are intimately united at their ends, as well as by their branches, but are not actually fused together. Although they seem to form long fibres with many nuclei, it is possible, by means of certain reagents to isolate the single cells, thus showing that the union is not complete. In two cases examined by Dr. Klein, it was found that there had been a partial separation of those cells, so that the muscular fibres were split into single cells, each containing a distinct nucleus. The deglutination had taken place along the horizontal lines of Eberth, which correspond to the lines of junction of the single cells, the amount of separation varying considerably.

The evident result of this loosening of the union between the individual cells is feeble muscular action, the rapidity of the contractions being markedly lessened. The author, from a study of the two cases observed by him, and of three others reported by Dr. Przewoski, in which the same changes were noted, comes to the following conclusions:

1. The deglutination of the cardiac cells may take place independently, or as a consequence of other changes in the musculature of the heart.
2. When this alteration involves a large portion of the heart-muscle, it may cause sudden death independent of other lesions.
3. It is met with as a secondary change in the course of acute febrile and zymotic diseases, as a consequence of mechanical interference with the circulation, and in cases of chronic myocarditis.
4. When the deglutination is very marked, involving many cells, though not over a very extensive area, the lesion may lead to rupture of the heart.

MULES' OPERATION FOR EVISCERATION OF THE EYEBALL.

Enucleation of the eyeball, performed according to the usual method, is very disfiguring in its results; the glass eye which is subsequently inserted having only a very limited movement, and being almost useless as far as concealing the deformity is concerned. Mr. Mules some time ago introduced a new operation which, he claims, obviates this disadvantage, so that it is almost impossible to detect the loss of the natural eye. By this method the sclerotic, with its attached muscles, is left in the orbit, so that the movements of the glass eye are nearly perfect.

The successive stages of the operation are thus described by Dr. Sydney Stephenson, in *The Hospital Gazette* of August 18, 1888:

1. An incision is to be made with a narrow-bladed knife, all round the periphery of the cornea, at its junction with the sclerotic, and the entire cornea removed. The inner and outer extremities of the wound are to be shaped so that when the wound is sutured the incision will lie evenly.
2. With a scoop, or other convenient instrument, the contents of the globe are to be removed. The greatest care must be taken to leave no trace of choroid or other internal structure behind. The internal surface of the sclerotic coat should be left white and glistening.
3. Bleeding must be checked by well irrigating the cavity with either cold or very hot 1 to 4,000 bichloride solution, and by pressure with small aseptic sponges.
4. When all bleeding has ceased, a glass sphere, of which several sizes are made, must be introduced into the scleral cavity. Mr. Mules has invented an ingenious instrument for this purpose, but if a sphere be used considerably smaller than the cavity—and this should always be done—difficulty is seldom met with.
5. The sclerotic, with its superincumbent conjunctiva, is united over the glass sphere by three or more silk sutures introduced vertically. Silver sutures should not be used for this purpose, as they are difficult and painful to remove.
6. To prevent excessive reaction, Mr. Mules burrows

deeply with the point of a pair of scissors into the orbit at the outer side of the globe, and introduces a gold wire into the hole thus made.

7. All the parts are thoroughly syringed with a 1 to 4,000 bichloride solution, and iodoform is sprinkled over the wound. A dressing of salicylic ointment, spread on lint covered with cotton-wool, and a bandage, are then applied.

If all proceed satisfactorily, it is unnecessary to dress the eye for three days, and when dressing is needed the bichloride solution and iodoform should be used freely. The sutures may be removed when the wound has healed. Some pain and swelling of the conjunctiva, lids, and face may follow the operation, but in the course of a week, or ten days, a perfect and very movable stump remains. An artificial eye may be fitted in from three to four weeks after the operation.

It has been urged as an objection to the operation that the glass ball might get broken in the orbit. Such an accident, which might undoubtedly occur, would be very serious, although, fortunately, no such accident has yet happened. Another and more serious objection is, that a foreign body is introduced into the eye, and there is no certainty that it will always remain innocuous. It is true the operation is a favorite one with several excellent English ophthalmic surgeons, yet it is one that cannot be recommended until a long experience has proved its safety. The loss of the second eye, and consequent total blindness, which might possibly result from sympathetic disturbance, could not be compensated for by the improved appearance of the glass substitute for the eviscerated organ.

News of the Week.

The Medical Examining Board of Virginia.—Dr. J. Herbert Claiborne, Jr., of this city, writes: "To the Editor of The Medical Record. Sir: In your issue of October 6th you refer to the Medical Examining Board of Virginia. In your comments you say: 'It is well known that an effort has been made by the Faculty and Students of the Medical College of Virginia to change the law so as to exempt Virginia graduates from its provisions. This is a confession of weakness unworthy, as it seems to us, of the colleges of that State. If the local institutions cannot educate students sufficiently to pass the Board examinations they had better go out of the business.' Your correspondent freely agrees with you in the sentiments expressed in the above quotation from your editorial, but he would distinctly call your attention to the fact that *only* the 'Medical College of Virginia,' as represented by its Faculty and students, has made any effort to change the reading of the law so as to exempt Virginia graduates from its provisions. The Medical Faculty of the University of Virginia have never made any such effort, and an intimate acquaintance with the sentiments of this body convinces your correspondent that they never will. It is safe to say that the sentiments of the Faculty of the University of Virginia are echoed in this respect by those who have the honor to claim this institution as their *alma mater*. As your comments stand, one who is not acquainted with the history of this movement in Virginia would be quite certain to assume that some other medical college had participated in this effort to have Virginia graduates exempt from the provisions of the law. It is but right to call your attention, and that of your readers, to this matter."

Thanks.—The New York Medical Record, with its usual enterprise, devoted its entire edition of September 22, 1888, excepting one page, to a report of the proceedings of the Congress of American Physicians and Surgeons, and of the special societies that met in conjunction with it, in Washington, September 18th, 19th, and 20th. This is a valuable index to the proceedings, and will undoubtedly be in large demand outside of its regular subscription list.—*Buffalo Medical and Surgical Journal.*

"Sulfonal" and not "Sulfanol."—Dr. B. Sachs writes: "The name of the new hypnotic was unfortunately distorted in my recent article. The o and a had been interchanged. Sulfonal, and not sulfanol, is the correct spelling."

Death of Dr. E. Williams, of Cincinnati.—We regret to have to announce the death of the well-known Cincinnati oculist, Dr. E. Williams.

Sir Morell Mackenzie's Book Seized.—The Berlin authorities have taken the surest way to prove that Mackenzie's book contains evidence against official classes difficult to refute, by seizing it. It is stated that forty thousand copies have been taken by the police.

M. Paul Gibier, of Paris, who was sent to investigate the yellow fever last year in Cuba and South America, passed through this city last week on his way to Florida.

The Violence of the Yellow Fever continues to decline; the number of new cases daily ranges between twenty and thirty, with three or four deaths. The whole number of cases up to October 15th was 3,569, with 316 deaths.

The Congress for Criminal Anthropology holds its second annual session in Paris, August 1st to 8th, under the presidency of Professor Brouardel.

The Italian Pediatric Association is the name of a new national medical society recently organized at Rome.

Another Addition to Bellevue Hospital is a handsome chapel and library, which is now in course of erection, and which is the gift of Mrs. R. H. L. Townsend, the lady who last year presented to the institution a cottage devoted exclusively to operative procedures on female patients.

Sued for Malpractice for giving Chloroform in Eclampsia.—Dr. J. J. Leppa, of this city, has been sued for malpractice. The plaintiff, an Italian woman, says that her brother, the patient, a boy of fifteen, went to work at his trade in a silk-twine and braid factory in the morning, and came home at noon complaining of a pain, and was shortly after seized with convulsions. She called Dr. Leppa, who gave him chloroform and ether. The boy had six successive convulsions. The anæsthetic brought him out of each, but at the end of the sixth he died. It is a well-known fact that chloroform is one of the best and most approved drugs in eclampsia; and this case seems to be a particularly unjust one.

A Dinner was given to Dr. David Ferrier and Mr. Victor Horsley at the University Club, on the 11th inst., by several neurologists and surgeons of this city.

Dr. A. H. Smith gave a reception to Dr. Sansom, of London, on the 5th inst. It was largely attended by the representative medical men of this city.

Our Scholarly and Interrogatory Contemporary the American *Lancet* comes out this month with the query, "The Union of Medical School and University—What is the Advantages?" One advantage would be a wider knowledge and deeper knowledge of syntax, a gradual disappearance of the correlation of plural nouns with singular verbs, and adscititiously, perhaps, the infusion of acumen into the minds of proof-readers and printers' devils.

Charity and the Paupers of New York.—According to the Charity Organization Reports of this city, there were, in 1886-87, 92,582 persons applicants for, or dependent on, charity. A critic of this report works over the figures and finds that we have only about 27,918 dependent families in the city, representing perhaps 100,000 people of all ages. If this is the limit of the dependent class, why is it that about 250,000 depend upon charity for their medical services at dispensaries, and over 40,000 depend upon charity for medical services in hospitals. There can be no doubt that there are between 90,000 and 100,000 families in this city who apply for, or more or less depend upon, charity.

Professor Zuckerkandl, of Gratz, has been appointed Professor of Anatomy at Vienna, to succeed the late Professor Hyrtl. Professor Ebner, of Gratz, has been appointed to the Chair of Histology.

A Woman Without a Vagina or Perineum.—Dr. Bonnain, in *L'Union Médicale* (Canada), was summoned to an obstetrical case, and found the labor over and the child alive and well. On examining the patient he found an extraordinary state of affairs. "Picture to yourself, in short, that with this unfortunate woman, not as the result of an obstetrical mishap, but as a fault of conformation, there was neither anus, nor perineum, nor fourchette, nor vulvar ring, nor sphincter of the vagina, nothing in short of that which constitutes that barrier, sometimes so difficult to pass, which is called the inferior strait. The whole was replaced by a frightful chasm, whose dimensions, particularly from above downward, were really immeasurable. The natural result of this was that the large baby, which during my examination was quietly sleeping near us, had had no difficulty in getting out of his prison."

Another Disease of Women.—Dr. Lindner, of Neuwied, has just written a book on floating kidney, and he asserts most emphatically that it is a frequent trouble in women. One out of every five or six has floating kidney. Dr. Lindner, in examining the patient, always stands to her right side. He places the right hand against the anterior abdominal parietes, and presses the left against the back of the lumbar region, so as to press the kidney forward. The patient is then placed on her side, with her knees drawn up. By sharply shaking her body the kidney, if movable, will fall forward. In some cases Dr. Lindner did not detect the abnormality till after repeated examinations. He finds that floating kidney affects the peculiar nervous organization of women more or less unfavorably; but he is opposed to operative measures, excepting when the patient's life is endangered, which must at least occur very seldom. He has collected records of thirty-six nephrectomies and twenty-nine nephrorrhaphies. Dr. Lindner is a great believer in the treatment of floating kidney by careful bandaging.

An Intercolonial Medical Congress is to be held at Melbourne, in 1889.

Doctors of Medicine in Germany and in America.—During the academical year 1886-87, the twenty Universities of Germany conferred the degree of Doctor of Medicine on 847 candidates, as against 689 in the previous corresponding period. During a similar period the 117 medical colleges of the United States graduated 4,000 students. This is a great country.

The Coccus of Acute Bright's Disease, which has been expected for a long time, was born to science in Vienna recently. Dr. Julius Mannaberg, working in Nothnagel's clinic, has found a new streptococcus in the fresh urine of acute Bright's disease, and not found in two hundred examinations of urine in forty-five other patients not "Brightiques." Dr. Mannaberg has cultivated, inoculated, etc., his coccus and concludes: In the majority of cases of acute Bright's disease the streptococcus is found in large quantities in the fresh urine, which was not the case in the urine of healthy persons, or those affected with another malady. The pure cultures of this microbe essentially differed from all other micro-organisms hitherto described. The injection of this streptococcus into the blood-vessels of rabbits and dogs produced an inflammatory lesion of the kidneys, whereas the other organs were only exceptionally affected. With these results he believes he has proved, with a certain degree of probability, that certain forms, and perhaps all the forms, of the idiopathic acute Bright's disease had a bacteriological foundation.

Experimental Entomology.—It is stated that a laboratory of "experimental entomology" has lately been established in the Cornell University, with the object of investigating the action of insecticides on noxious insects. While seeking for a means of exterminating the Colorado beetle and kindred scourges, travellers on the Continent and dwellers in London lodging-houses may, perhaps, be permitted to hope that the workers in this useful field of research will extend their philanthropic efforts to the suppression of meaner forms of insect life, which add a good deal to the sum of human discomfort.—*British Medical Journal.*

Medical Practice in Arizona.—First doctor—"Got back already from Arizona?" Second doctor—"Yes; I don't like it out there." "What's the matter?" "If you have a case of small-pox and don't report it to the Board of Health, you are fined and imprisoned. If you do, the relatives fill you full of buckshot. It ain't a healthy country for a young doctor."—*Medical Standard.* In this city the methods are more refined; instead of using shot-guns the relatives bring a suit for damages.

NEW YORK STATE MEDICAL ASSOCIATION.

Fifth Annual Meeting, held at the Hotel Brunswick, New York, October 9, 10, and 11, 1888.

(Continued from p. 460.)

Thursday, October 11th—Third Day, Afternoon Session.

DISCUSSION ON PUERPERAL SEPTICÆMIA.

Dr. Carlton C. Frederick opened the discussion. Were micro-organisms invariably found in the bodies of women sick with puerperal septicæmia? In the affirmative of this question stood the names of Myerhofer, Fetty, Caze, Waldeyer, Rindfleisch, etc. The micro-organisms were always similar or identical in form. Doleris maintained they could be discovered in the blood by persistent search.

Despite various arguments which had been presented in substantiation of the specific nature of puerperal septicæmia, the tendency of modern research had been to prove that the puerperal poison was of a septic nature, and the points of entrance to the body were generally through the wounds of the genital canal. But, clinically, it seemed probable the germs of the disease might enter the blood through other channels, as the respiratory or digestive tracts; otherwise certain epidemics could not be explained.

There was abundant proof that the contagium of some of the zymotic diseases might produce in the puerperal woman a form of febrile disease undistinguishable from puerperal septicæmia and presenting some of the characteristics of the specific disease from which the infection was derived. This opinion had been accepted and opposed by men of equal eminence.

Puerperal septicæmia occurred more frequently in primiparæ than multiparæ, and its frequency bore some proportion to the number of channels laid open favoring absorption.

The number of puerperal cases had diminished in lying-in hospitals more than in private practice, demonstrating the advantages of antiseptic precautions.

If the conditions of puerperal infection were always the same, puerperal septicæmia would always pursue the same course. But such conditions varied greatly, as did also the course of the disease The prognosis varied with the character and intensity of the affection as well as with the individuality of the patient. The further entrance of germs should be prevented by cleansing the wounds, immediate union of lesions after labor, not too frequent examinations during labor, all precautions of cleanliness, irrigation of vagina, and when a dead fœtus had been delivered and in certain manipulations within the uterus, irrigate that organ with bichloride solution, 1 to 4,000. Further particulars in treatment related to diphtheritic patches, fever, etc.

Dr. Everard D. Ferguson, replying to the second question, whether there was a specific febrile disease peculiar to the puerperal woman, said that puerperal fever was a surgical septicæmia; that an essential fever, as scarlet fever, small-pox, etc., was the same disease whether occurring in a pregnant or non-pregnant woman. There remained certain cases, however, which were due to a common zymotic cause, and others due to toxic agents generated in or belonging to the body of the patient. Pregnancy did not afford immunity from any one of the infectious diseases. Mere severity of zymotic diseases in the puerperal patient did not necessarily imply infection through the genital tract. In general the zymotic diseases ran an aggravated course when they developed in women in childbirth, but the essential nature of the diseases was not changed.

Dr. Herman M. Biggs discussed Question 1, "What facts can be cited in support of the doctrine that the puerperal febrile diseases owe their origin to the action of the micro-organisms?" and said these diseases were so manifestly infectious in nature, and had been so long recognized as such, that argument seemed superfluous.

Their bacterial origin had become an acknowledged fact. The manner of infection was of great interest. The microbes necessary to the development of puerperal infection existed, according to Doleris, in all normal vaginæ, and in all cases wounds for their entrance into the blood existed after labor. But the microbes met with many difficulties in healthy patients in their attempt to infect the system; and prevention might be effective by washing out the vagina; cleanliness during and after delivery. The difference in the virulence and nature of the organisms bringing about infection, difference in resistance of the individual and in conditions surrounding the patient and of parts through which absorption took place, would explain differences in course and severity of the disease in different cases.

It could be said that in puerperal febrile diseases we had a class of affections closely allied to surgical septic diseases, with similar anatomical and pathological characteristics, and presenting the same organisms. Puerperal fever occurred only in conditions permitting infection.

Dr. S. B. Wylie McLeod, in continuing the discussion, said puerperal fever was a septic disease, depending on a variety of causes, but in most cases it was identical with surgical septicæmia. He believed there was an etiological relation between zymotic and some forms of puerperal fever, and the relation seemed similar to that between typhoid and malarial fever in so-called typho-malarial fever.

Dr. F. W. Ross classified the causes of puerperal fever as follows: The condition of the woman, her susceptibility to septic influences, conditions surrounding her, foreign influences conveyed by the attendant. Considering the fallibility of man, he would answer the question, Were there any antiseptic measures which under all conditions could be relied upon as prophylactic to puerperal septicæmia? in the negative.

Dr. John Shrady maintained that the rôle of the microbe in the animal economy was not as yet understood in all its bearings, that many of the conclusions were without logical links. He thought that statisticians in a measure diminished the mortality by contracting the classes; that the placental separation during labor left a wound which presented a sufficient absorbing surface, without considering the minor tears and abrasions made by the accoucheur. He advocated the avoidance of all possible solutions of continuity, but would make other causes as well bear the opprobrium of disaster. He certainly believed that cleanliness was next to godliness, and that the system should be put upon the defensive, and would advise the employment of antiseptic measures so that there might be no impugnment of deeds even though faith be absent. He asked, however, if the temple which had been built was founded on a rock?

Dr. Frank Grauer, speaking of pathology, said if critics asked what was puerperal fever, he would ask, in tnrn, what was surgical fever? Then there were varieties of surgical fever as there were of puerperal fever. If it were said surgical fever was septicæmia, was that not begging the question, for we must still ask, what was septicæmia. If septicæmia caused surgical fever, might it not produce a fever of the same character in the lying-in woman? Septicæmia required two factors, the poison and the blood which received the poison. He claimed the poison had not been proven not to vary in different cases, and the blood was never the same in any two individuals; consequently the symptoms varied both in surgical and puerperal fever. Dr. Grauer went on to give the pathology of puerperal septicæmia.

Dr. W. T. Lusk discussed the treatment. The history of the Maternity Hospital offered excellent evidence of the value of aseptic conditions in reducing the percentage of cases of puerperal diseases. Formerly in that hospital the mortality from septic diseases was from two to three per cent., but since the introduction of prophylaxis, including Garrigue's pad, septic disease was unknown. The same prophylactic measures, should they become commonly employed, would likewise lessen the number of septic cases in private practice. It required only a few simple measures, of no great bother to the physician or patient: Surgical cleanliness, soap and water, nail-brush, corrosive sublimate, 1 to 1,000 for the hands, carbolic acid, 1 to 1,500 for instruments, corrosive sublimate solution employed to cleanse the vulva, thighs, and lower abdomen of the patient, and perhaps an injection of sublimate solution into the vagina as a safeguard against infection. Unnecessary examinations should be avoided. In the third stage, secure complete removal of membranes. The technique in closing wounds made during delivery was not difficult. The Garrigue pad should be worn after delivery. Patients thus handled did not have septic fever. Some recommended the use of the intra-uterine douche whenever the temperature went above 100° F., but such practice was based on ignorance and was not justifiable. The indication for the uterine douche was not the temperature. When the organ was large and flabby, contained coagulæ, gave a fetid discharge due to retention of portions of membranes, and fever attended prolonged operations in the uterine cavity, or a dead fœtus was born, the douche should be employed, consisting of carbolic-acid solution. Two quarts was sufficient. It should not be repeated every four hours, as had been suggested. Three injections were seldom called for. Wounds of the genital tract should be touched by a caustic. He was a firm believer in the vaginal douche, which, with care, could be given with safety when symptoms developed.

The discussion of treatment was continued by Dr. R. L. Banta, and a paper on the subject by Dr. A. S. Carroll was read by title.

Adjourned.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN SURGERY.

Stated Meeting, October 8, 1888.

Robert Abbe, M.D., in the Chair.

CANCER OF THE BREAST IN A MAN.

Dr. Charles A. Powers presented the patient because of the rarity of cancer of the breast in the male. The man was about seventy years of age. The family history was negative. About eighteen months ago he fell heavily on the sidewalk, striking the right arm and right side of the chest, which was ecchymosed. Twelve months later a hard lump appeared in the right breast. Dr. Powers saw the patient in July, 1888, at which time the tumor was half the size of a man's fist, involved the upper and outer region of the right breast, was circumscribed, and of stony hardness. The skin was retracted about the nipple, the axillary glands were markedly enlarged. July 20th he removed the breast and axillary contents. Convalescence was rapid. Dr. Ferguson pronounced the tumor typical cancer. An interesting point in the case was the development of cancer directly from traumatism. He had found that during the past ten years one hundred and seventy cases of cancer of the breast had been admitted at the St. Luke and New York Hospitals, and of these but one was in the male. Dr. Gross had found about two per cent. of the cases of cancer of the breast to be in males.

Dr. John Ridlon read a paper entitled

THE EARLY DIAGNOSIS AND RATIONAL TREATMENT OF LATERAL CURVATURE OF THE SPINE,

WITH DEMONSTRATION OF EXERCISES AND PRESCRIPTIONS ADAPTED TO THE VARYING CONDITIONS,

by Claes Enebuske, Ph.D., M.G.

Dr. Ridlon said that upon the early diagnosis and rational treatment of the conditions presenting, would depend the successful termination of a case of lateral curvature. When the distortion had advanced so far that the diagnosis had been made by the dress-maker, it might fairly be said to have passed the time for an early diagnosis, and generally for a complete eradication of the deformity. It was not easy to say how early the disease could be diagnosticated. He thought it would depend upon the cause of the curvature, since upon this would depend the first symptoms. A curvature depending upon one of the fevers, scarlatina, etc., would present early symptoms, differing greatly from those of a curvature following pleurisy, although when well advanced the distortion in either case was similar. A curvature depending upon shortening of one lower extremity would in its early symptoms differ from one due to polio-myelitis anterior. In short, a case might begin with curvature and rotation; or without curvature; or without rotation; or without either curvature or rotation, and still present diagnostic symptoms. An early diagnosis could be characterized as such when there was yet no deformity of the spine, or only such deformity as could by posture be temporarily eradicated. A deformity which at the first examination could not be made to wholly disappear, would generally resist treatment so far as removal of the primary curve was concerned.

By rational treatment they meant an attempt to meet indications as presented by causation and symptoms in each individual case, with the end constantly in view to restore the figure, as far as possible, and to so strengthen the muscles that this contour might easily be maintained. Routine treatment of any kind was to be deprecated. Rotation of the vertebral bodies, causing the convexity and concavity, was the characteristic symptom of lateral curvature, and in a large number of cases appeared very early; but even before this rotation could be detected there were in some cases characteristic symptoms: as the patient walked, unconscious of being observed, the head was carried somewhat to one side, the shoulder of that side was somewhat advanced, and the corresponding foot was rotated out. Where the lateral deviation appeared before rotation, as in curvature depending upon one short lower extremity, he had not found the neck and shoulder symptoms and the outward rotation of the foot. It might be asked whether a true scoliosis could be caused by a short leg or a contracted pleural cavity, and he would answer, in the present state of uncertainty as to the etiology of true scoliosis, that lateral deviation of the spine, with rotation of the vertebræ, and all the characteristic forms in the late stage, might follow a short leg or contracted pleural cavity.

For the sake of clearness in arranging the symptoms, they divided the cases into two classes: 1, Those that presented rotation before curvature; 2, those that presented curvature before rotation. The symptoms in these two classes were given, with numerous photographic illustrations. The deforming symptoms might go on progressively to almost any degree, or they might cease to progress at any time either with or without treatment. The distortion in some cases took place very slowly, covering upward of ten years, while in others the same degree of deformity was reached in a few months. In the second class, of those in which the curvature preceded rotation, they had not found outward rotation of the foot and the peculiar advanced shoulder during locomotion that was so often present in the first class; the lateral deviation of the head appeared subsequent to the lateral deviation of the line of the spinous processes. It was very doubtful if true mammary atrophy occurred in cases of the second class, but they had observed a smaller, though not a flabby gland on the side of the convexity. Some considerable number also presented a condition of flat-foot. The spinal rigidity came slowly as compared with the other class of cases, and so far was more amenable to treatment. In cases in which there was a short lower extremity, there was an advantage in having the length equalized by a high shoe. But this was not absolutely necessary for a good result.

The treatment should consist in the reduction of the deformity, and the development of the muscular strength to maintain the acquired position. This was gained by posture, manipulation, massage, and gymnastics, with assistance and resistance. In many cases electricity was of use; the proper arrangement of the clothing was of no small importance; but of more importance than any other one thing, was constant maintenance by voluntary effort, both during the exercises and between them, of the best possible position. As to the use of braces, supports, jackets, and corsets it was difficult to lay down any uniform law. In some cases they were unnecessary, in some even harmful, while in some they were a great comfort to the patient; but it should not be forgotten that their use was prejudicial to muscular development and delayed the ultimate favorable result.

Claes Enebuske, Ph.D., M. G., then demonstrated a number of exercises which patients with lateral curvature of the spine were required to practise, differing according to the indications in the several cases. The exercises should never be carried to the point of fatigue, and should be adapted to the patient's ability; many of them were performed with assistance or resistance from the surgeon, but voluntary effort was required in all cases, even were paralysis present. No exercise should be performed with arrested breath. The following were some of the exercises demonstrated in a case which had been under treatment for some time: 1, Forward-bend-lean, standing, arm-stretching upward and aside; 2, left-stretch, right-wing, stride forward-bend, sitting, raising of the trunk with pressure and resistance; 3, standing, circumduction of the arms; 4, left-stretch, right-wing, hip-lean, stand, bending to the right, with pressure; 5, forward-bend-lean, standing, arm-raising, aside, upwards, etc.

Dr. L. A. Sayre being called upon to open the discussion, said he was very glad at last to find the doctrines which he had taught for thirty years beginning to make an impression. About three years ago his son demonstrated exercises similar to what he had just witnessed, and he had for years taught that in lateral curvature proper gymnastic exercises were essential in the treatment, and that all machinery, whether consisting of the plaster-of-Paris jacket, iron brace, or whatever else, was of no use, but injurious, excepting as an aid in maintaining improved position. If gymnastics were adopted early enough there would be no need of machinery of any sort. He said proper gymnastic exercise, but it was almost impossible to describe what that was. The exercises demonstrated during the evening were only a few which might be employed, and it was almost impossible to classify or write them in a book. The exercises had to be adapted to each case separately; find out what muscles required development, and then apply electricity, manipulation, beating of the muscles, voluntary movements, etc., as might be indicated. He did not believe that when the bones had changed their form that they could be made straight by any treatment. But there was one essential in the treatment of lateral curvature, namely, self-suspension, for in that position the deformity was less evident than in any other. It was possible, however, to carry the muscular development to extremes, as ocurred in the case of a doctor who increased the measurement of his chest fourteen inches in two years. Where machinery was required he had found nothing as valuable in retaining what had been gained by exercise as self-suspension and the application of the plaster-of-Paris corset. He had never seen any machinery which did not produce more irritation than the plaster jacket applied properly during self-suspension; but if one could get the patients for treatment early enough more could be done by physical training without any mechanical support.

Dr. Gibney inquired of Dr. Sayre how he determined, when a patient first came to him, whether he should or should not wear a jacket.

Dr. Sayre replied that he could not tell when the patient first came whether it would be necessary to put on a jacket. He never put it on until he saw that the patient could not get along and improve without it.

Dr. Judson agreed with Dr. Sayre in emphasizing the importance which should be attached to the remarkable reduction of deformity, amounting in mild cases to absolute restoration of symmetry, which attends placing the patient in suspension by the scapulæ and humeri. He could not escape the conviction that the longer a patient's body is kept in a symmetrical position during the growing period, the better the chance for removing deformity or preventing its increase. We thus take advantage, as in many other forms of orthopedic treatment, of the child's growth If the deformity and disability are unmolested in the growing period, they increase with the growth of the child. If they are removed or lessened during the growing period, the natural increment is so much added on the side of ability and symmetry.

In regard to the value of active exercises such as had been exhibited, if the affection is but the local expression in the vertebral column of a general weakness, as may be inferred from the lassitude and the harmful effects of fatigue exhibited by some of his patients, he thought that a limit would soon be reached in the effectiveness of muscular exercises. His plan of treatment was based on the avoidance of fatigue, and the assumption for as many hours in the twenty-four as is practicable of those positions in which the deformity is lessened. He favored suspension by the hands and the axillæ and the supine position with lordosis maintained by an air-pillow. The latter position may be maintained in some patients during the hours of sleep.

Dr. Gibney being asked his opinion of Bernard Roth's method of treatment by exercise, said he was practically a convert to it. He had been pleased to hear Dr. Sayre's remarks, for it had been stated by those who were advocates of Roth's method that Dr. Sayre, in the use of his plaster-of-Paris jacket, undid exactly what he had attempted to do by exercise, and they had claimed that he put the jacket on nearly all of his cases as soon as they came for treatment. Dr. Gibney was glad to learn that Dr. Sayre did not apply the corset in all cases, but first tried gymnastic exercises, and failing to make any improvement under this, then gave the support of the jacket. The greatest obstacle in treatment by systematic gymnastic exercises was met in cases of elderly persons whose modesty forbade them taking the exercise in classes usually composed of young people; and in factory girls who, in spending their time in this manner, were taking it from the hours of sleep. He now refused to take patients for this treatment unless they would submit to daily exercises for a month under directions of a teacher. Bernard Roth did not claim to correct the rotation of the spine; even in the best cases he had failed to notice any marked improvement in rotation; but by great enthusiasm he got his patients to walk and sit correctly, or in the most favorable position, until it was done instinctively, thereby strengthening the weak muscles and greatly improving the patient's appearance.

Dr. Reginald Sayre dwelt upon the importance of the patient fixing his attention upon desired movements, even though he was unable to perform them, as in some cases of paralysis, and it had to be done entirely by the physician or instructor. A patient should not be excused from exercises because he complained of lassitude.

Dr. Lewis Hall Sayre thought supporting jackets should never be applied as long as steady improvement followed exercises. But many cases which had gone on to marked rotation, while improving under gymnastics to a certain point, yet after a time came to a stand-still, and the jacket worn at intervals between the exercises would prove of benefit and not interfere with the development of the muscles. Of course the jacket itself restrained muscular movement somewhat, but by maintaining the improved position which had been gained by muscular exercise, it took off the strain from the muscles, prevented them from becoming overtired, and thus aided their development. He did not believe the rotation was ever much improved.

Dr. Ketch stated that two years ago he had read a paper giving the statistics of two hundred and twenty-nine cases of rotary lateral curvature of the spine, and much to his surprise had found that over fifty per cent. of the cases were in children under seven years. Those spoken of this evening had been mostly in adults. He thought that if the treatment in these cases had been begun early, in childhood, the results might have been better. After rotation had progressed to a certain point we could do no more than by exercise to improve muscular tone, and through that maintain a better position. If children were regularly examined much might be done to prevent and relieve lateral curvature.

Dr. Anderson, of Brooklyn, had the assistance of a corps of teachers, and among them they taught gymnastic exercises to about fifteen thousand pupils each week, and it was interesting to see the beneficial change come over the physique of the little ones. They recorded the height, weight, etc., and particularly the outline of the body from head to foot. After pupils had attended school two years they almost invariably found the right shoulder a trifle lower than the left in right-handed persons. They had, therefore, instituted exercises and positions for the correction of that tendency. They could take a perfectly formed boy, and by training make him deformed within six months. But if a child took only twenty minutes' obligatory gymnastic exercises a day, and was permitted the remainder of his school hours to assume injurious positions, one might expect deformity. But exercises three or four times a day in the school-room would tend to keep the spine straight.

Dr. A. M. Phelps thought one mistake had been made, the whole argument having been directed toward muscle. He believed that in a large majority of cases of lateral curvature of the spine the difficulty was not primarily in the muscle, but in the bone. Even in the child at the desk the change was in the bone, for it sat in a position to favor absorption of one side of the body of the vertebra. Deformity high up in the dorsal region was often of rachitic origin, and do what one would to develop the muscles, the deformity would remain and often continue to grow worse. If the trouble was primarily in the bone, and not in the muscle, it was clear that treatment should be directed not to the muscles but to the bone. Dr. Ridlon had spoken about short leg producing the deformity. He believed that was certainly a mistake, for he had very seldom found one leg short in cases of lateral curvature of the spine. The shortness of one leg was only apparent, as was the case when a weight was swung from the anterior superior spinous process of the ilium to the floor, the patient twisting the pelvis slightly without moving the feet the weight would touch the floor, but on standing erect, facing directly forward, it would swing free from the floor. The plaster corset or brace did not produce atrophy of muscles if gymnastic exercises were continued. Dr. Phelps took exception to calling the exercises those of Roth, for Roth had simply borrowed them from the Swedes and Germans. Moreover, Roth had not cured one case by such exercises, and the apparent improvement in position was due to the patient's becoming fatter. The plaster jacket was best, excepting, however, one which he had obtained from the Russians. This consisted of veneer of spruce glued in layers of linen and made to accurately fit the body. It was thin, strong, and very light.

Dr. Taylor said he had also been accused of employing mechanical means unduly, but he wished to disclaim it, since many of his cases received no mechanical treatment at all, requiring only exercise and hygiene. They employed artificial respiration, which he thought padded out the thorax from within, where the deformity was most accessible. Then, among other Swedish movement-cure methods, they employed lateral suspension, making the fulcrum the greatest point of the convexity. Where the back was flexible he thought the rotation could be somewhat reduced. The patients should give up much mental work, and children should lie down some minutes in the afternoon.

Dr. A. Jacobi, having listened to the discussion, thought it well to remember the fact that to the vertebral column there was attached a child or adolescent. It had appeared to him that too little attention had been given to the individual; nearly all had been given to the vertebral column. Some years ago scoliosis was scarcely known in this country; now it is common. It had been admitted that lateral curvature was rarely cured after adolescence. We should, then, give attention to children, especially those which showed any tendency to rickets. The trouble was first with the bones. The specialist should remember that there were general causes for local diseases. Particular attention should be given to dietetic treatment and healthy school surroundings. He mentioned one drug in particular which had proven of value in rachitic subjects, namely, phosphorus, but not phosphates.

Dr. Ridlon closed the discussion, and said. concerning short legs, that he had seen this deformity very seldom in lateral curvature of the spine.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, October 5, 1888.

Francis P. Kinnicutt, M.D., President, in the Chair.

Dr. Beverley Robinson presented a patient suffering from an

INTRA-CRANIAL LESION,

whose history, as obtained from his wife, was as follows: James D——, aged twenty-eight, formerly worked in a hardware store. His habits were fairly good, and he had never had epilepsy, syphilis, or any other serious disease. A year ago last August he was struck by a base-ball over the outer portion of the right eyebrow. The blow caused a small flesh wound and some discoloration around the eye, but the man did not lose consciousness. He had a headache for a few days which was severe enough to keep him at home. At the end of this time the headache disappeared and he apparently recovered his health perfectly. Six months later his wife noticed that his speech was becoming affected, and it was soon so thick and "tangled" that she could not understand him. He used incorrect words, and when told the right ones could not always repeat them correctly, although he would make some sounds resembling them. He did not know himself that he made use of the wrong words, nor did he seem always to understand what was said to him. He could write nearly, if not quite, as well as before. At the same time that the difficulty in speaking appeared the patient became very irritable, taking offence on the slightest provocation, striking his wife and children, and menacing them in various ways. He was also very somnolent. He had a very noticeable tremor, and there was some paresis of the left arm and leg; he was, however, able to walk about, although he fell to the ground on several occasions. On one or two days, at this time, there was such extreme weakness of the left lower extremity that the patient was unable to stand erect, and the left leg was also rigidly extended (tonic spasm?). About one month after the beginning of these symptoms the patient was suddenly attacked with a tonic epileptoid convulsion, limited to the left side of the body. This convulsion was repeated once the following night, but has never since reappeared. There was no aura, no biting of the tongue, and no loss of consciousness. For a period of about a month the mouth and chin used to twitch frequently, and at times, off and on, ever since the accident the wife had noticed that the right pupil was larger than the left. The sight was good, there was no strabismus, and examination of the fundus showed it to be normal. About seven months ago the patient suffered greatly from headache, specially marked in the right occipital, frontal, and temporal regions. There was also frequent vomiting at that time. The headaches lasted for about three months. There was some deafness for about two months, and it was noticed also that the patient sweated considerably.

Examination.—The right pupil is dilated and responds sluggishly to light. There is no strabismus. The patient can stand well on both feet, though not on either alone. He drags his left leg slightly in walking. The left arm and hand tremble somewhat, and are weaker than the right. The tongue, when protruded, points a little to the left with marked tremor. There are no other signs of facial paralysis, no anæsthesia nor analgesia, and no abnormal sensations in any part of the body. The speech is indistinct, though the patient articulates single letters fairly well. There is no derangement of the bowels or bladder. The patient writes his name very distinctly.

During the past few days he has been taking potassium iodide, and has improved greatly.

The question of special interest in connection with the case, Dr. Robinson said, was whether the cerebral symptoms presented had anything to do with the injury received six months before they appeared.

Dr. C. L. Dana said that it was difficult to express any positive opinion as to the nature of the lesion present, but, taking into consideration the fact of an injury and the subsequent symptoms, the case looked like one of local encephalitis.

Dr. A. H. Smith questioned whether the blow had anything to do with the trouble. He did not think that a blow over the frontal sinuses, not fracturing the bone, was likely to cause sufficient traumatism to give rise to such marked symptoms.

Dr. Sansom said that the fact of an injury on the right side and of motor symptoms on the left side was sufficient, in his opinion, to lend at least probability to the belief in some causal relation between the two, although the question was a difficult one to decide. Whatever the cause, there was undoubtedly some lesion present in the right hemisphere. Yet it was interesting that there should be aphasia, as Dr. Robinson, in reply to a question, had stated that the man was right-handed. It seemed as though there must have been some radiating lesion which had passed off. He was inclined to think that there was some degeneration going on in the brain, a sort of sclerosis, perhaps.

Dr. William M. Polk thought that, with such a history and such symptoms, one would be justified in trephining; yet it was precisely in cases such as this that the consulting together of the physician and the surgeon was of indisputable advantage. The physician was needed to advise the surgeon as to whether, in a certain case, an operation were justifiable.

Dr. Robinson said that he had been unable yet to study the case as carefully as its interest and importance warranted, but, as far as he had formed an opinion, he was inclined to regard the condition as one of pachymeningitis. He did not think there was an abscess present.

Dr. Sansom, referring to the question of operation, said the mistake often made was in hesitating too long. It was better at least to attempt to do something in these cases than to let the patients die unrelieved.

Dr. Kinnicutt thought that Dr. Dana's suggestion was worthy of consideration. Suppuration can take place in the cerebral tissues while all symptoms may be latent for a long time. He related a case of cerebral abscess in which for a considerable period there were no definite symptoms, after which the patient grew worse, and then apparently better again. He finally died, and at the autopsy an abscess was found in the brain.

Dr. Peabody reported a case in which middle-ear disease had existed for forty years, symptoms of brain trouble having occasionally been manifested during that time. At the autopsy a cerebral abscess was found.

Dr. William M. Polk then presented a number of

GALL-STONES, REMOVED BY OPERATION

from a patient, a lady, who had suffered for a long time with obscure gastric symptoms.

Dr. V. P. Gibney then read the paper of the evening (see page 472), entitled

JOINT DISEASE AND CONSTITUTIONAL TREATMENT.

Dr. Robinson agreed with the author of the paper in his doubts concerning the efficacy of medicinal treatment of this class of diseases.

Dr. Dana asked whether the author did not belive in the utility of certain drugs, such as mercury and iodine? The latter was regarded by many in the light of a specific in tubercular diseases.

Dr. Gibney replied that he did not think these drugs did much good, notwithstanding the reputation which they enjoyed.

Dr. Peabody said that he had been much interested in the parallel between chronic joint disease and pulmonary tuberculosis. Such an idea had often occurred to him, but he had never formulated it to himself in exactly that way.

The Society then adjourned.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

MR. BRYANT'S RECENT LECTURES AT THE COLLEGE OF SURGEONS—THE CASE OF DR. GLOSTER—THE WHITECHAPEL MURDERS—PHARMACY AND PHARMACISTS—AMALGAMATION OF THE SANITARY INSTITUTE WITH THE PARKES MUSEUM—DR. POORE ON HYGIENE

London, September 29, 1888.

In his recent lectures at the College of Surgeons on "Cranial and Intracranial Injuries," Mr. Bryant emphasized anew the importance of estimating all injuries of the head with reference to the risk of the cranial contents being involved—either primarily or secondarily. As a practical deduction from this view, Mr. Bryant pointed out that if in every grave, or, indeed, apparently uncomplicated example of head injury associated with more or less complete paralysis of at least one of the brain functions, such as was indicated by unconsciousness, the surgeon recognized to the full the force of the fact that the brain, as a material organ, was bruised or otherwise injured, a line of treatment was likely to be at once suggested which could best favor the restoration of the injured part toward health. Physiological and mechanical rest would stand foremost, with the administration of nourishment simple enough to maintain the normal powers and help repair, and not stimulating enough to excite action. Everything in the form of alcoholic stimulants or solid meats should be forbidden. This line of treatment should be continued for weeks—possibly for months—the severity of the injury and the primary symptoms forming the surgeon's best guide to a decision. This method of treatment would also be adopted under the wholesome dread of exciting, by sins either of omission or of commission, the one common complication which the surgeon should have ever before him, viz., an inflammatory action in the injured organ. Experience spoke in no feeble terms that this action was readily started and with difficulty quelled, and that it was by such inflammatory changes in the injured brain that most head cases, simple or severe, were brought to a fatal termination. Mr. Bryant observed that these views were taught at Guy's Hospital thirty years ago by the late Mr. Hilton, a former teacher and colleague of his. Mr. Bryant went on to say that should symptoms of intracranial irritation or inflammation show themselves, they should be dealt with actively, as, from the nature of the brain and its membranous coverings, the process, when once started, soon spread. In the early stage, the application of cold to the head by means of a Leiter's metallic tube was the most efficient local measure, and free purgation, with very low diet, the most effective general treatment. If the inflammatory action were great, a free bleeding from the jugular vein or from the arm was strongly to be advocated, and this operation might, in many cases, be repeated with much advantage. The lecturer said he was convinced that he had saved lives by this treatment. In chronic cases the value of mercury taken internally could not be doubted.

Considerable satisfaction is expressed in medical circles at the acquittal of Dr. Gloster, a medical practitioner of Kensington, who has just been brought to trial on a charge of having caused the death of a patient by procuring criminal abortion. The patient was poor, and no fee, it was admitted, had been offered to Dr. Gloster. There was, therefore, no pecuniary inducement for his having acted as alleged. Almost the only evidence against him was an alleged "dying declaration" on the part of the patient. The judge, however, decided that this could not be received as evidence, as there was no reason to suppose that the patient, in making the statement, knew that she was on her death-bed. The post-mortem examination disclosed that the patient was not pregnant, but that the uterus had been injured by an instrument of some kind, which, however, although introduced within the os uteri, had never entered the uterine cavity at all, but had passed upward through the posterior wall of the uterus emerging close to the summit of the fundus. A piece of dressmaker's wadding was found lying in the peritoneal cavity. It is difficult to imagine that such a wound could have been caused by any operation performed by a medical man, with ordinary care and skill. Dr. Gloster, however, had had special experience in obstetric and gynecological work, as he would have been enabled to prove had the trial proceeded. Among other witnesses prepared to testify in this respect on his behalf was Dr. Lombe Atthill, of Dublin, who had come to London expressly to give evidence. The deceased (a married woman separated from her husband) believed herself to be pregnant, and had solicited Dr. Gloster to procure abortion. He had declined, and had, it was proved, desired her not to come to his house again. It is supposed that the injuries found after death were self-inflicted, and that the so-called "dying declaration" (made by the patient at a time when she was not aware of her critical condition) was made out of personal pique against Dr. Gloster for refusing to comply with her wishes.

All England has been horror-struck with the series of murders recently committed at the East End under peculiarly revolting circumstances, and apparently with impunity, for no culprit has yet been discovered. The victims in each case have been women known as prostitutes, and in the last two cases the bodies have been mutilated by the murderer in a most barbarous manner. In the last one of all, the abdomen had been opened and the intestines removed and placed by the shoulder of the deceased. The uterus and its appendages, with the upper part of the vagina and the posterior two-thirds of the bladder, had also been removed from the pelvis, and, as no trace of these parts could be found, it is presumed that they were taken away by the murderer. The incisions were cleanly cut, avoiding the rectum, and the vagina was divided low enough to avoid injuring the cervix uteri. The natural deduction is that the murderer must be a person with some anatomical knowledge, but further than this no clew to his identity has yet been found, nor any motive for the crime discovered. It has, indeed, been suggested that the murderer is a lunatic, and that this and the previous murders are the work of the same person; but as yet this is pure conjecture.

Many will be ready to echo with approval the views put forward lately by Mr. F. B. Benger in his presidential address to the British Pharmaceutical Association. The address was chiefly devoted to the relation of pharmacy to pharmacists, and the question of education and training. A more extensive preliminary examination was urged. Considering the close relations of pharmacy to medicine, the question of elevating the status of pharmacists in any way is one fertile in interest to medical men. It must, however, be confessed that while, on the one hand, the bulk of general practitioners in this country continue to dispense their own prescriptions, and, on the other hand, counter-prescribing by chemists is the rule rather than the exception, there must be some antagonism between the two classes. There are, it is true, medical men in general practice who do not dispense, and there are also some high-class chemists who steadily set their faces against counter-prescribing, but they are in the minority. A more complete separation of the two professions, as in many other countries, would tend to the elevation of both. As it is, the public are often inclined to look upon the ordinary practitioner as being but little, if anything, above a tradesman, and they are so accustomed to regard non-dispensing as one of the characteristics of a consulting physician that they sometimes regard a non-dispensing general practitioner as almost the equal of a *bonâ fide* physician in consulting practice.

The amalgamation of the Sanitary Institute with the Parkes Museum has been successfully carried out, and the union of the two institutions bids fair to add to the prosperity of both. On Tuesday last an audience of nearly a hundred assembled to hear Dr. Vivian Poore deliver the first of a series of twelve lectures, designed especially for the benefit of sanitary inspectors. The lecturer urged that the greatest of all sanitary evils was overcrowding, and that the professional sanitarian would scarcely be needed if it were not for the fatal tendency of populations to concentrate in towns. The science of sanitation, he said, was practically the science which enabled persons to live in crowds with the least amount of damage to themselves. We must not lose sight of the fact that big schemes of water-supply and sewerage tended indirectly to cause a concentration of population in itself most undesirable. It was doubtful if this overcrowding of buildings could be prevented; but, unless it could, one must have serious doubts as to the permanency in the improvement in health in our large towns. Death-rates were often very misleading, especially in regard to so mobile a population as that of London.

OUR PARIS LETTER.

LESSENING THE DANGERS IN OVARIOTOMY—ETIOLOGY OF TETANUS—AN INTERESTING CASE OF RUMINATION—PASTEUR INSTITUTE.

(From our Special Correspondent.)

PARIS, September 28, 1888.

AT a recent meeting of the Academy of Medicine, Dr. Polaillon exhibited an enormous tumor of the ovary of the right side, which he had removed from a woman aged thirty four. The tumor weighed six kilogrammes and a half. He took the opportunity of pointing out the danger of washing out the peritoneum during ovariotomies and analogous operations practised on the abdomen. He observed, in the case under notice, and in others before, a suspension of the respiration, and a syncope almost fatal occurred during the act of washing, owing to the water employed extending to the upper regions of the abdomen, and particularly to its contact with the inferior surface of the diaphragm. To attenuate this danger, Dr. Polaillon recommends: 1. That the patient to be operated on should be placed in an inclined position, the chest being raised above the level of the hips, so that the washing be limited to the hip and to the lower part of the abdomen to prevent the water reaching the diaphragm.

2. The temperature of the water employed should never be higher than that of the body. 3. The anæsthetic administration of chloroform should be particularly attended to.

After having passed in review the divers theories entertained on the etiology of tetanus—to wit, the nervous theory, the humoral theory—Dr. Richelot, Jr., declares himself a convinced partisan of the theory which admits the infectious and contagious nature of this malady. In support of this theory, Dr. Richelot communicated to the Academy two interesting cases which recently came under his own observation. In the first case the patient was a young woman, aged twenty-one, who was operated on at the hospital on June 15th for a salpingo-ovaritis, and about a week after she was affected with tetanus, which carried her off in forty-eight hours. A few days later another young woman, aged twenty, was admitted into the hospital who was also affected with a salpingo-ovaritis of a grave character. She was operated on, July 5th, and on the 11th she was suddenly seized with sharp pains in the left abdominal region. At the same time, she suffered from a sore throat and was seized with trismus and tonic convulsions. The patient died on the 13th. Nothing abnormal was found in either case at the autopsy. That the second case was infected by the first there seemed to be not a shadow of a doubt for Dr. Richelot, but how the first patient got affected with tetanus he was rather embarrassed to say; the more so as, according to the more recent theories, the origin of tetanus is attributed to the horse. In the cases under notice he could trace no relation between them and that animal.

In connection with this subject, it may be interesting to reproduce here the following note on the infectious nature of traumatic tetanus, recently published in the "Archives Roumaines." Traumatic tetanus of the horse and of the mule is at least sometimes, if not always, an infectious affection, transmissible to animals, and very probably to man. During the evolution of the affection a virus is developed and multiplied, which virus, injected into the cranial dura mater of another animal, produces the same infectious affection. This virus is found in the bull, and in the spinal marrow of the animal primarily affected with the disease. Analogous to the rabic virus, its virulence may be augmented by the sub-duramatric inoculation in series. Like the rabic virus, it is susceptible of attenuation by desiccation in the air, at a moderate heat, and, like the rabic virus also, its effects are more intense when it is inoculated under the cranian dura mater than when it is inoculated in the skin or in the muscles of the back. The author, Dr. S. O. Shakespeare, reserves his conclusions relative to the prophylaxy of inoculations with attenuated virus (*Le Courrier Medical*, September 1, 1888).

The following case of rumination is related in the *Petit Journal de la Santé*: A patient, in consulting Dr. Dehio lately for a bronchitis, related that he was subject to a sort of eructation which brought up to his mouth aliments he had taken a little time before and which he remasticated to enable him to swallow them again. The patient's parents were healthy, and had never had anything of the kind. This anomaly first began at the age of twelve, after an attack of intense and persistent whooping-cough, each fit of coughing being followed by vomiting. Till the age of sixteen each meal was accompanied, without exception, with the rejection of aliments corresponding in quantity to that of an alimentary bolus, and that without effort, without pain or nausea, and altogether involuntarily. Moreover, it was with pleasure that the patient masticated for the second time the aliments regurgitated. The operation took place at different times, the rejection commencing a quarter of an hour after meals and continuing for nearly an hour afterward. The aliments were not modified, milk was the only thing that was brought up in a coagulated state, there were no gaseous eructations; in fine, digestion was quite satisfactory, and the process still goes on as usual.

The construction of the Pasteur Institute is far advanced, and the opening is announced for an early date. It is situated in the Rue Dutot, within a few yards of the Boulevard Vaugirard. It has an imposing appearance, the principal wing of the building being reserved as a residence for M. Pasteur, who, it is said, will be lodged in a most sumptuous manner, thanks to the generosity of the subscribers to the work. The other parts of the main building contain a comfortable apartment for M. Roux, M. Pasteur's principal assistant. There are also a library, laboratories, halls for conferences and inoculations, and, finally, an amphitheatre, rather small in proportion to the other parts of the building. At the back are to be seen folds, dog-kennels, hutches for rabbits, aviaries—all these being rather scanty. To the left is the laboratory where the virus is to be manufactured. The waiting-rooms are rather too near the halls for inoculation, as the operation might produce an unpleasant impression on those who present themselves for treatment. It is said that some of the rooms will be reserved for pensionnaires, and, as observed by a French critic, it is to be hoped that this institute, contrary to the intentions of the subscribers and founders of the work, will not become the hostelry of rabies, after having been a palace.

THE VAGINAL TAMPON.

To the Editor of The Medical Record.

Sir: Speaking of the vaginal tampon, as discussed in your late issues, a fact has been omitted to which much importance should be attached. The presence of unhealthy secretion is a potent factor of vaginal and uterine irritation, and the tampon that obstructs its egress may support the uterus, but create an evil in another direction by provoking congestion and ulceration, or aggravating existing soreness with an acrid pent-up fluid. Hence the tampon that facilitates escape for the discharge is the least objectionable. As to the shape, no standard can be observed; it must vary and adapt itself to the necessities as indicated to the surgeon's judgment. If sufficient elasticity and pliability in the material be obtained, the necessity of methodical exactness in regard to the form of tampon is precluded. It will adjust itself to the parts to be filled simply by care in packing. The tampon made wholly of absorbent cotton is doubtless the softest and most pliable or perhaps soothing that can be applied, and yet one of the worst in use for the very reason that it does not in any degree retain these properties. It takes up moisture, it is true, but while the thin, watery fluid oozes through, the viscid humor—if there is any—remains behind. But a few hours suffice for it to become thoroughly saturated in a comparatively healthy vagina, then it not only loses all elasticity, lessens in size, drops out of place, and renders no service, but creates much mischief by acting as an irritant. Wool and absorbent cotton make a much better tampon, inasmuch as elasticity is secured; but if uniform pressure, consistent bulk, and free vent for offending secretion are desired, we fail in the object in proportion to the amount of absorbent cotton used, for the same reason that the cotton alone is useless.

I agree with Dr. H. I. Ostram, that all tampons present features of imperfection, but the nearest approach to one responding to the requirements, and obviating the objections here presented, is to be found in the refined or dressed oakum. I have been in the habit of using the coarse material which I deemed preferable to other substances for most purposes. But since employing the dressed oakum, I have acquired results superior to those obtained by the use of other agents. It corrects fetor, and gives tonicity to the parts, thus improving the quality of, and lessening unhealthy discharges. Æsthetically it is cleaner and neater, offending less by its odor than other material when removed. It can be medicated as other substances when desirable, and formed into any shaped tampon required. It is elastic, pliable, porous, absorbent, affording better means of exit for discharge, and parting with thick humors more readily. And irritable sores are more tolerant of its contact because of its healing properties.

M. F. McTaggart, M.D.

St. Helena, Cal., September 25, 1888.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from October 7 to October 13, 1888.

Meacham, Frank, Major and Surgeon, died at Fort Douglass, Utah, October 9, 1888, at twenty minutes past one P.M.

Maus, Louis M., Captain and Assistant Surgeon, by direction of the Acting Secretary of War, is relieved from duty at Fort Schuyler, N. Y., and will report in person to the commanding officer, Fort Porter, N. Y., for duty at the post. Par. 10, S. O. 236, A. G. O., Washington, October 10, 1888.

Spencer, William G., Captain and Assistant Surgeon, by direction of the Acting Secretary of War, granted leave of absence for two months. Par. 11, S. O. 236, A. G. O., Washington, October 10, 1888.

Davis, William B., Captain and Assistant Surgeon, by direction of the Acting Secretary of War, granted leave of absence for six months. Par. 12, S. O. 232, A. G. O., October 5, 1888.

Banister, John M., Captain and Assistant Surgeon, by direction of the Acting Secretary of War, the leave of absence granted to him in S. O. No. 210, September 10, 1888, from this office, is extended one month. Par. 2, S. O. 232, A. G. O., October 5, 1888.

Official List of Changes in the Medical Corps of the United States Navy for the week ending October 13, 1888.

Bates, N. L., Medical Inspector. Detached from the Pensacola, and placed on waiting orders.

Farwell, W. G., Surgeon. Ordered to U. S. Receiving Ship Franklin.

Scott, H. B., Passed Assistant Surgeon. Detached from the New York Navy Yard, and ordered to the Naval Hospital at Mare Island, Cal.

Magruder, A. F., Surgeon. Ordered to duty at headquarters of the Marine Corps.

Chloroform-water as a Solvent for Drugs.—Dr. Unna (*Therapeutische Monatshefte*, July, 1888) has employed the antiputrefactive power of chloroform-water for the preservation of solutions of drugs for subcutaneous employment. When a solution of chloroform-water is injected under the skin a slight burning sensation is produced; but general action attributable to chloroform is but rarely produced. In many cases, however, no objective sensation follows the injection of chloroform-water in the gluteal muscles. Unna commends the substitution of chloroform-water for distilled water in the preparation of Fowler's solution, and all ergotine preparations, even when intended for internal use. He likewise recommends the addition of a few drops of chloroform to morphine solutions, and, in fact, he finds it preferable to dissolve all alkaloids, whether intended for internal or external use, in solutions of chloroform-water.—*Therapeutic Gazette.*

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 13, 1888:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	46	12
Scarlet fever	81	16
Cerebro-spinal meningitis	1	1
Measles	83	8
Diphtheria	73	20
Small-pox	0	0
Yellow fever	0	0
Cholera	0	0

The Sixty-first Meeting of German Naturalists and Physicians.—This meeting was held in Cologne from the 17th to the 23d ult. Among the subjects and papers for the Section of Medicine were: "The Phenomena of Irritation in Spinal Diseases," by Prof. Naunyn; "Ankylostomum Duodenale and Anguillula Intestinalis, with Demonstrations," by Prof. Leichtenstern; "Pathology of Speech," by Dr. Ewich; and others. In the Section for Surgery some of the more important subjects set down are perhaps of greater interest and include: "The Results of the Treatment of Peritonitis and Peritoneal Sepsis," by Dr. Witzel, of Bonn; "The Importance and Value of Capillary Aspiration of the Bladder," by Dr. Rosenberger, of Würzburg; "Six Cases of Surgery of the Brain and their Treatment, with Demonstrations," by Dr. Flothmann, of Bad Ems; "The Treatment of Acute Purulent Osteomyelitis at the Epiphysial Line," by Dr. Thelen, of Elberfeld; "On Utilization of the Doctrine of Cerebral Localization Surgically Considered," by Dr. Heusner, of Barmen; "On Infection with a Sound Skin," by Dr. Schimmelbusch, of Cologne; "Extirpation of the Bladder, or Total Excision of the Vesical Mucous Membrane," by Dr. Brohl, of Cologne.

Fuller reports will be given later.

Hospital of the University of Pennsylvania.—Amputation of the Thigh by Professor Von Esmarch, of Keil, and Demonstration of the Physical Examination of the Heart by Dr. Sansom, of London, at the Hospital of the University of Pennsylvania, September 22, 1888. Professor Esmarch and Dr. Priestly were introduced by Professor Ashhurst, in whose place Professor Esmarch operated for sarcoma of the knee. The operator applied his bandage up to the middle of the leg, spoke of the danger of driving cells upward if carried too far, and then bound the limb very tightly in the upper third of the thigh, using a two inch bandage, provided with an adjustable clamp. Von Esmarch had washed his hands antiseptically with great care, was dressed in a long, white operating dress, and washed the limb thoroughly before the bandage was applied. He used a long French knife; amputating at the lower third by a single circular incision, he severed the periosteum and sawed the bone. Dr. H. R. Wharton assisted and tied the arteries, and at Professor Esmarch's suggestion sutured the sheath of the sartorius muscle. Professor Esmarch then examined the tumor, which he pronounced a giant-celled sarcoma, and, as the disease had involved only the upper portion of the tibia, gave a favorable prognosis. The interior was full of cysts and blood-clots. The operator remarked that "in most cases of amputation I sew together the wound and apply the dressing before removing the constrictor," but said that in this case the veins were so much distended by the tumor that it was best to remove the bandage first. He also spoke of bleeding by paralysis of the vessels from compression. Professor Esmarch uses catgut ligatures and sutures, and usually no drainage-tubes,

APRAXIA AND APHASIA; THEIR VARIETIES, AND THE METHODS OF EXAMINATION FOR THEIR DETECTION.[1]

BY M. ALLEN STARR, M.D., PH.D.,

CLINICAL PROFESSOR OF DISEASES OF THE MIND AND NERVOUS SYSTEM, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

THE recent marvellous success of operations upon the brain, and the admission by surgeons that their chief guide in such operations is the presence of localizing symptoms, makes it incumbent upon all physicians to be on the watch for such symptoms. But many of the localizing symptoms require to be searched for, and are not directly complained of by the patient; *e.g.*, hemianopsia, and the hemiopic pupillary reflex recently described by Seguin. Hence it is not necessary to apologize for calling attention to the proper manner of examining a patient who presents one of the most interesting of all local symptoms, namely, aphasia. And I venture to do this before this audience, because of the recent discovery of certain defects of thought and memory associated with aphasia, and now named apraxia, which may not be familiar to those who have not given especial attention to the literature of nervous diseases. The study of patients who belong to the intelligent classes, who are able to appreciate, and become interested in and thus aid in special lines of examination, is open especially to the members of this Academy; and it is from such patients rather than from those found in hospital wards that information regarding these symptoms is largely to be obtained. It is, however, an exception to find in American literature reports of such cases, and I am convinced that this is due to the lack of appreciation of the importance of their careful study and examination, and publication. My object in this paper is not so much to present a review of our present knowledge regarding aphasia and apraxia as to indicate very briefly the methods of examination to detect *all* the symptoms present in patients suffering from these affections.

The division of disturbances of speech into the two great classes of sensory and motor aphasia—the first due to defect in the receptive and the second due to impairment of the emissive functions of the brain—has been followed by a further subdivision into several varieties. These are word-deafness, word-blindness, agraphia and motor aphasia, and paraphasia.

The accepted notion to-day is that every word in ordinary use has a complex mental substratum, which may be termed the word-image, made up of a number of memory-pictures. The memory of the sound of a word as spoken; the memory of the appearance of the word as printed; the memory of the muscular movements needed to write the word or to pronounce it, are known to be distinct from one another and yet to be associated together. Loss of one of these memory-pictures, or disturbance in their association, impairs the integrity of the word-image, and produces such defects in its use as are indicated by the names given to the respective varieties of aphasia. But, before considering these defects, let us look at the physical basis of the thought which lies back of the word. For the word is only a convenient means of expressing a thought, and thinking precedes language, as every intelligent observer of animal life knows, however Max Müller may regard the question. Objects and actions are the chief subjects of thinking, and their mental substratum is not difficult to discover. Take an example. This steel-pen has a certain shape and size and consistence which I see and feel. The shape and hardness perceived by eye and finger are associated and are remembered, and the mental substratum or idea of this pen consists of these two memory-pictures joined together. Other pens have forms of their own, and of them, too, I have a series of memory-pictures. But the idea of the object is only made complete when its use is known. And so to the memory-pictures of the pens is added another of the act of writing; itself a complex image, for that act has been watched and practised before being acquired, and its recollection involves the recalling of those memories of activity of which I have been a spectator or a participant. The mental image of the action is associated with the various mental images of different kinds of pens, so that it forms a common basis for the formation of a general idea of a pen as an object used for writing. And this idea, complex as it is, made up of numerous memory-pictures, is acquired by the mind through observation long before language is used. The baby may try to write before it can say "pen," or before it can describe the act of writing. The words, then, are added to the mental image to make it communicable to others, but are not essential to the idea.

A rose has, as its mental basis, a larger number of memory-pictures than a pen, for it has odor, color, taste, variety of outline and beauty; in fact every object, if thus analyzed, will be found to vary from every other in respect of the memory-pictures which form its mental substratum. What is true of these single words will be found to be true of every other, if the trouble is taken to analyze our subjective knowledge of them—an analysis full of interest, but aside from the present question. It is a fundamental position involved in the accepted theory of cerebral localization that memories are the residua of perceptions and are therefore localizable in the regions of the brain concerned in perception. It follows that these memories forming the idea of an object or an action, being distinct from one another, may be lost by disease of the brain having a limited extent, and that the character of the memories lost will depend on the location of the disease. Now cases have been recorded in which persons acted as if they no longer possessed such object-memories, for they failed to recognize things formerly familiar. A fork, a cane, a pen may be taken up and looked at by such a person and yet held or used in a manner which clearly shows that it awakens no idea of its use. And this symptom, for which at first the term blindness of mind was used, is found to extend to other senses than that of sight. Thus the tick of the watch, the sound of a bell, a melody of music, may fail to arouse the idea which it formerly awakened, and the patient then has deafness of mind; or an odor or taste no longer calls up the notion of the thing smelt or tasted; and thus it is found that each or all of the sensory organs, when called into play, may fail to arouse an intelligent perception of the object exciting them. For this general symptom of inability to recognize the use or import of an object the term *apraxia* is now employed. And since apraxia is a symptom which is very frequently associated with aphasia and which, in fact, may lie at the basis of aphasia, it should always be looked for in a patient. To test for apraxia it is only necessary to present various objects to a person in various ways and notice whether he gives evidence of recognition. Have him watched by his friends, and they will be able to tell whether he still chooses his articles of food at the table intelligently; whether he still knows how to put on his clothes, to use various toilet articles, to sew or knit or embroider if the patient is a lady, to admire pictures, or flowers, or perfumes, as before the illness began. The patient may or may not be able to name these objects; that, at present, is not the question. But is it evident that the object awakens an idea in the mind?

---

[1] Read before the Academy of Medicine, October 18, 1888.

The variety of apraxia known as blindness of mind is the one most commonly found, and it may not be uninteresting to recount one case of it, especially as that case affords the first example of its successful treatment by operation.

It is a case recorded by Macewen,[1] of Glasgow, and is as follows:

A man who had received an injury a year previously to his applying for treatment suffered from deep melancholy and strong homicidal tendencies which were relieved by paroxysms of pain in the head. There were no motor phenomena, but it was discovered that immediately after the accident, and for two weeks subsequently, he had suffered from psychical blindness. Physically he could see, but what he saw conveyed no impression to his mind. An object presented itself before him, which he could not make out; but when this object emitted sounds of the human voice he at once recognized it to be a man. In attempting to read, he saw what he considered must be letters and words, but they were unknown symbols to him; they conveyed no impression of their meaning; the memory of their signs was gone; it was a sealed book to him. These phenomena gave the key to the hidden lesion in the brain. On operation the angular gyrus was exposed and it was found that a portion of the internal table of the skull had been detached from the outer and had exercised pressure on the posterior portion of the supramarginal convolution, while a corner of it had penetrated and lay embedded in the anterior portion of the angular gyrus. Removal of the bone resulted in complete recovery from the pain and mental symptoms.

The variety of apraxia known as deafness of mind has recently been studied by Oppenheim,[2] of Berlin. He noticed that while some aphasics retain their musical faculties, others may lose the power to follow melodies, to appreciate music, or to hum or sing the tunes which they formerly knew. Thus, he relates that a patient of Finkelnburg, a flutist, noticed an impairment and finally a loss of power to follow notes, to play or to write notes, at the same time that he lost his speech. Ballet relates the case of a musician who suddenly lost his power to read music, and Kast one of a musician who suddenly became note-deaf; and Oppenheim gives histories of eleven such patients seen by him. That this is not a part of aphasia in any sense is proved by the fact that in many patients no such loss of musical power accompanies aphasia. In the well-known cases of aphasia recorded in this city by Ball and Seguin and by Amidon, it is expressly stated that the musical faculties were unimpaired. Granet tells of a patient who could say only one word, "pardi," and yet who could follow music, and not only sing the tune of the Marseillaise, but, while singing, pronounced several words, "patrie," "enfant," etc., which he could not say voluntarily; and Proust relates the case of a musician who could neither speak nor write, yet who could write a musical melody which he heard sung.

In view of these observations, it is worth while to test intelligent patients as to their musical faculties—their power to recognize tunes, hymns, melodies, their power to sing or hum a tune and to read or write music or play on various instruments.

Investigations of the power of a person to recognize and name an object by touch or taste or smell would be interesting, but have not often been undertaken. The loss of the muscular sense and consequent inability to perform delicate motions of the hands has rendered deaf and dumb persons who use their peculiar language of motion incapable of conveying their ideas; and if cases of this kind were more closely investigated some light might be thrown on the exact location of muscular sense. But all of us, by the feeling of many objects, can recognize them at once with our eyes closed, and thus arouse the memory-pictures of an object through this channel of sensation. Recently a case has been recorded by Farjes, in France,[1] of a gentleman afflicted with aphasia, who, though unable to name an object when he saw it, could do so when he felt it, thus proving that when one association is broken another may persist and be put to use. And in this connection mention may be made of cases, now several in number, of persons who, though unable to read letters which they saw, were at once able to name these letters correctly when they traced the shape of the letter with the finger, the muscular sense thus acting for sight and arousing the idea, and enabling the person to read, though he had true "blindness of mind."[2]

All of these facts are of great interest, not only as throwing light on mental processes of association, but as indicating that those processes are carried on in definite areas of the brain and in tracts which connect those areas, and can be arrested by disease in these parts; for in some of these forms of apraxia the situation of the lesion has been found. It is as yet too soon to make definite statements regarding such lesions. It seems likely that they lie in that *terra incognita*, the white matter beneath the cortex. And if the problem of the differentiation of cortical from subcortical lesions is ever to be worked out, it will only be after a number of cases, thoroughly examined as to all these processes, have been recorded, and autopsies to supplement the clinical record held. Let us see to it that when we get the autopsy it is not rendered useless by a failure in the examination.

One fact, however, of great interest, not formerly mentioned, to my knowledge, has been brought out by a study of the cases of apraxia which I have been able to collect and which are here tabulated—and that is, that that lesion has always been found in the left hemisphere in right-handed and in the right hemisphere in left-handed persons; in other words, in the same hemisphere lesion of which has produced aphasia. It is true that apraxia, like aphasia, has been noticed in cases of paretic dementia in which the disease is diffuse and is situated on both sides. This fact would not, however, imply that a unilateral lesion alone was insufficient to produce the symptom, and the nine cases with autopsy, here brought together for the first time, seem to establish the statement made.

Apraxia has as many varieties as there are organs of sensation. The variety which existed in the nine cases tabulated was that of psychical blindness, and accompanied the form of aphasia known as word-blindness. In all the cases the lesion involved the cortex of the supramarginal and angular gyri, or the tracts posterior to these parts in the white matter beneath them. It is probable, from the association of psychical deafness with word-deafness, that it is due to lesions in the upper temporal convolution, but autopsies are wanting. It is noticeable, however, that this symptom of apraxia is always associated with some form of aphasia. Hence all cases of aphasia should be examined for apraxia. It is well known that lesions in the right hemisphere in right-handed, as the left hemisphere in left-handed, persons do not produce aphasia. In the accounts of cases of such lesions, I have not been able to find any account of the discovery of any form of apraxia. It seems, therefore, that at present we must

locate our memory-pictures of objects on one side of the brain; and on the same side which presides over speech. This appears to be very strange, since the bilateral connection of each sensory organ with both hemispheres is proven. There appears to be no reason why the appearance of things, their sounds, tastes, odors, etc., should not be received and remembered in both hemispheres instead of in one. But, as a fact, they are not. And the fact remains as mysterious as the corresponding fact regarding speech-memories.

Turning now from this investigation as to the condition of the memory-pictures of objects in the brain which together form the idea of a thing, let us look at the second set of memory-pictures which make up the word-image. As already stated, the word makes the idea available for thought and for its communication. The word "pen" or "rose" brings to a focus a number of various sensory images. But the word itself, in its ordinary use among intelligent persons, involves several of the senses. Words are heard, read, spoken, and written; and each of these processes goes on in its own brain-area, in which area, therefore, distinct residua of the process or memory-pictures of the word lie. Hence each word is composed, as far as its own image goes, of four separate memories, each of which may be lost separately.

1. If the memory of the sound of the word is lost, the word cannot be called to mind and cannot be recognized when heard. Show the patient a watch and he is unable to name it; tell him it is a stone, a match, a watch, and notice whether he dissents from the former and gives signs of satisfaction at the last. If he does, he has only auditory amnesia but not word-deafness. If not, he is word-deaf, and is unable to understand what is said to him. The lesion lies in the posterior half of the first and second temporal convolution in the left hemisphere in right-handed; in the right, in left-handed persons. This is one variety of aphasia whose lesion is well known, though it rarely occurs alone.

2. If the memory of the appearance of the word is lost, the visual image of it cannot be called to mind or recognized, and then the patient will be unable to write spontaneously, for he cannot remember how the letter looks which he wishes to write; and he will be unable to read because the shapes of the letters and words seen arouse no recollection. As a matter of fact, words are forgotten more easily than letters, and if a patient is to relearn to read he must begin with letters and go on to words. Figures are sometimes recalled when words are forgotten, and many a patient can do mathematical calculations on paper who cannot read or write ordinary words. Such patients may also play cards or other games if they are not psychically blind. It is not infrequently the case that persons who are thus word-blind can read aloud, can write at dictation, or copy, and yet show no evidence of understanding what has just been read or written. A distinction must be made between those who can and cannot do these things, though its pathological basis is still obscure. The condition of visual amnesia with word-blindness is due to a lesion involving the supramarginal convolution and angular gyrus, and is often associated with psychical blindness, but may occur independently of it. It was present in all the cases of psychical blindness enumerated in the table, and in the cases tabulated in Table II. Word-deafness and word-blindness frequently occur together, and then the lesion is found involving both the temporal and the angular convolutions. About forty cases are now on record, with autopsies, which prove this assertion. Two of the cases here cited illustrate this combination.

3. If the memory of the effort needed to pronounce a word is lost, a true paralysis of articulation occurs, though the muscles may not be weakened. This is the ordinary form of motor aphasia, due to a lesion of Broca's centre. It is to be noted that such a loss of speech involves a loss of the power of repeating words after another, as well as of voluntary speech, and is not accompanied by any inability to understand spoken or written language. In the uneducated, as in children, the acts of talking and writing are closely joined, as may be seen by watching the lips, which move in the act of writing. But among those accustomed to write much these acts are independent, and it is probable that many educated aphasics may be able to answer questions in writing when their efforts at speech fail. Reading aloud will also be lost in motor aphasia, for here, too, the inability to articulate hampers the patient.

4. The independence of the effort-memory necessary for writing and connected with movements of the hand from the effort-memories of speech has been alluded to. When these are lost alone the condition is known as agraphia. In such a state the pen cannot be used. Copying, writing at dictation, and voluntary writing are all lost. It has been noted already that when a word cannot be called to mind it of course cannot be written. But words can often then be written at dictation, if the person is one who writes much. Hence sensory agraphia and motor agraphia must be distinguished; the former being a part of word-blindness, the latter not at all as-

sociated with inability to read. The lesion of motor agraphia is unsettled, though a few facts point to the posterior part of the second frontal convolution as the probable seat of this function. It is not unlikely, however, that the more exact localization of fine movements of the thumb and fingers in the posterior central convolution by Horsley may be followed by the discovery of the writing centre in this vicinity. As it is still unsettled, it becomes incumbent to test every patient as to his powers of writing voluntarily and at dictation, and of copying.

These forms of aphasia are due to a loss of distinct memory-pictures. These several memory-pictures which are united in the word-image may thus be reasonably regarded as separate from one another in their location in the brain. But since they *are* joined together to form the word-image, it follows that the association-fibres joining the various areas are as necessary to the use of even a single word as the various areas with their memories. It is really by association only that an object or a word becomes a subject of thought or use. To a man who understands English only, the word "cloche," as seen or heard, conveys no idea. Form an association with that word by telling him that it is the French for "bell," and he at once possesses an idea. Or, to put it in another way, cut off from the auditory word-memory "bell" all its connections with sight, sound, feeling, and effort memories—isolate it completely—and when the word bell is heard it no longer means anything. Such complete severance of association-fibres is the probable explanation of some cases of psychical blindness and deafness, including word-blindness and deafness. And when the condition is complete it will, of course, be impossible to distinguish between a loss of the memory-picture and an isolation of the memory-picture. The condition may, however, be incomplete. A man suddenly unable to read at sight is able to recognize letters by tracing them with his forefinger. What does this mean? It is evident that he has a visual memory of the letter, for he can, under certain circumstances, arouse that memory and recognize the word. But he cannot arouse it directly by sight. He has to do so indirectly through muscular sense. Is it not evident that the association of the visual memory-picture with the general visual area is cut off, but its connection with the muscular sense area is preserved; and so, by way of the latter, it can be reached? The association with the word-hearing and word-writing memories in these cases is commonly preserved, for the man could write at dictation or write spontaneously, yet was unable to read what he had just written. All the associations with that visual memory then were intact but one, and that one the one commonly used in reading, namely, from the common sight centre in the occipital lobe to the angular gyrus. Thus analyzing the condition subjectively we reach the conclusion that in such a case some defect in definite associations was present. In four such cases now on record a deep-seated lesion within the occipital lobe underneath the cortex has been found after death,[1] lying in such a position as inevitably to affect seriously the association-fibres passing to the angular gyrus.

Again, it has been noted that the power to recall the name of objects was often lost when the patient was able to recognize that name when heard. It is in a serious and permanent degree the same trouble which we are all liable to when we fail to recall the name of a man whom we know. In such a condition of auditory amnesia the memory or mental echo of the word is not lost, because when the word is heard it is recognized. The memory-picture remains, but is inaccessible by the ordinary way. The sight of the object does not call it up. But, in such a case, if the object be handled or smelt or tasted—or heard, if that is possible—the name may come to mind. Thus the voice of the man may cause us to recall his name when his face has not done so. In other words, if one association-tract is impervious others may be open, and before it can be stated that the memory-picture is lost all the ways to it must be tried. I am not aware that any autopsies can be found to support the theory that auditory amnesia is due to lesion in the association-tracts leading to the temporal convolutions, in distinction from word-deafness due to lesion in those convolutions. But, judging from the facts known regarding word-blindness as distinct from visual amnesia, there is a probability in favor of this theory. Here, again, we are met with the difficulty that previous examinations of cases have been incomplete even when autopsies have been secured.

5. There is one form of aphasia in which the lesion is known to affect a great association-tract; viz., paraphasia, or the aphasia of conduction of Wernicke. In this condition the word-hearing and word-uttering process is perfect, but their connection is broken. The patients can understand what is said to them and can pronounce many words well. But they misplace words, use one word for another; *e.g.*, call, as one of my patients did, the card four of spades the "five of telephone." Such patients may even talk jargon. In such a case it is impossible for the person to repeat a word after another, yet he may be able to speak the word, like the patient who, after trying in vain to say no at the request of the physician, finally gave it up and, shaking his head sadly, said, "No, no." The lesion in these cases usually involves the island of Reil and severs the fibres beneath it which join the temporal and frontal lobes with one another.[1] This power of repetition should, therefore, be tested invariably. A somewhat similar condition of defective writing and copying, in which words are mispelled or are unintelligible, has been recognized clinically, but its lesion is not yet known.

It is therefore evident that the processes of association should be most carefully tested. Such acts as reading aloud, writing at dictation, or copying, may be mentioned as involving the function of a few of the association-tracts, and these should be investigated, as well as those already named.

In many cases of aphasia the symptoms are not such as to point to one of these pure forms of aphasia; a combination of the characteristics of these forms will be found. The patient then has a mixed form of aphasia in which both sensory and motor elements are combined. But in such cases a thorough examination will demonstrate that one or the other pure form is present in excess, and this will indicate in which direction the lesion lies. The fact that all the various speech-areas are supplied with blood by the middle cerebral artery, and the frequency with which an embolus lodges in this artery instead of plugging a small branch of it, explains the frequency of mixed aphasia and the rarity of pure forms—which are due to small areas of softening.

To examine an aphasic thoroughly it is neccessary to test:

1. The power to recall the spoken or written name of objects seen, heard, handled, tasted, or smelt.
2. The power to understand speech, and musical tunes.
3. The power to understand printed or written words.
4. The power to speak voluntarily. Does he talk clearly? does he mispronounce words? does he misplace words? does he talk jargon?
5. The power to repeat a word after another.
6. The power to read aloud. Does he understand what he reads?
7. The power to write voluntarily. Can he read what he has written?
8. The power to write at dictation.
9. The power to copy.
10. The power to recognize the use of objects seen, heard, felt, tasted, or smelt.

The following cases illustrate some of the varieties of aphasia here described, and present interesting features:

---

[1] Wilbrand: Seelenblindheit, p. 180; Claus: Irrenfreund, 1883, p. 82; Dejerine: Progrès Médical. July 31, 1883; Broadbent: Med.-Chir. Trans., 1872, p. 162.

[1] Cases of Wernicke, l. c; Dejerine: Rev. de Méd., 1885, p. 174; Starr: Amer. Jour. of the Med. Sci., 1884, Case 99.

Case I. *Word-deafness and word-blindness.*—S. B——, aged sixty-five, right-handed, was suddenly seized with aphasia during the night of April 20, 1888. His wife on waking found him on the floor, acting strangely, saying, "What is the matter with me," and in distress, but conscious and not paralyzed. For the next three days his wife thought that he was out of his head, for he paid no attention to what she said, and could only say one word—"hook." Then the use of words began to return, and he talked better and better. He complained of numbness in the right side, and said that he could not understand her. He seemed himself, but she was unable to get him to answer questions, as he could not comprehend what she said to him. His general health has been about as usual, but he has kept quiet, as going about among people bewilders him. He is always worse in the morning on rising.

Examination on May 14th failed to reveal any sensory or motor disturbance, excepting a slight deviation of the tongue to the right. Reflexes equal on both sides; pupils equal and react normally. The existence of hemianopsia could not be determined, as he could not be made to understand what was sought, and experiments were ambiguous in results, as he was very watchful of all tests. Hearing good; central vision good. Loud aortic direct murmur, with hypertrophy and dilatation of the heart, which was rapid and irregular. The aphasia was tested carefully. As far as the power of articulation and of the spontaneous use of words was concerned he had no loss. He talked freely and rapidly when he could be made to talk at all, and often made remarks of his own accord; *e.g.*, while I was testing his sensation to cotton, he said, "I feel you touch me, if that is what you want to know." As far as the power of writing spontaneously or handling the pen was concerned there was no loss, for he wrote his name clearly, and he also wrote words and figures fairly well. He therefore did not present the symptoms of motor aphasia nor of agraphia.

His power of understanding spoken or written language was, however, almost entirely abolished. He had a bewildered look, and turned to his wife constantly for aid when spoken to, though he did not seem to understand her any better than me. To all such commands as, "Shut your eyes," "Show your tongue," "Stand up," "Sit down," "Put on your glasses," he remained wholly indifferent, listening attentively, but not obeying until the idea was conveyed by gestures, when he at once understood and acted accordingly. To ordinary questions he gives no appropriate answer; sometimes, however, when he sees that a reply is awaited, he says, "I don't understand you;" "I would answer you if I knew what you wished to know." The only method of arousing any comprehension is to repeat a single word over and over, when he sometimes understands. Thus when the word "name" is repeated he at last seems to get the idea, and says, "Oh, my name; yes, my name is S. B——." To several subsequent questions he gives the same reply, and seems puzzled that I should ask, as he supposes, the same question again. The word "age," repeated, elicits the answer, "Sixty-five, sixty-seven," and he appears uncertain as to the exact number. When asked his address he does not reply, but when it is repeated gives his name again, then his age, and only when the words "Long Island" are repeated several times does he get the idea. Then he gives his full address at once correctly. There is, therefore, almost total word-deafness. His auditory memory of the names of objects is also impaired, for when various objects were shown him he failed to name many of them, though after several attempts he occasionally succeeded. He appeared much perplexed at his failure to name objects and so much distressed that tests were not pursued. The power to recall names, as well as the power to recognize words, was therefore much impaired. Since it was impossible to obtain replies to spoken questions, written questions were put to him. And this elicited a remarkable symptom. He read to himself or aloud all that was written, easily and rapidly, but failed utterly to understand what he read. To very few of the written questions did he show any evidence of intention to reply. In one or two, a single prominent word read several times aloud awakened an idea; thus, "When did this begin," was answered by, "I don't know whether I can tell you; it was the twentieth of April, I think." "Where do you live?" he read three times aloud, and then answered by giving his name. Other questions were equally lost to his understanding. It was evident that word-blindness as well as word-deafness was present, and in about an equal degree. This condition of word-blindness appeared to prevent his writing freely. The only thing he could be got to write was his name; and this he wrote again and again when attempts were made to make him write at dictation or copy. In fact, he could do neither of the last two even when the idea was conveyed to him by gestures. He succeeded a week later in copying a few figures, but was unable to add them up, though formerly a good accountant. The word-blindness was therefore associated with visual amnesia.

The condition was therefore one of pure sensory aphasia, word-deafness and word-blindness being combined; but no disturbance of utterance, no misplacing of words, no hesitancy in reading aloud being present.

The diagnosis of embolism of the terminal branches of the left Sylvian artery, producing anæmia and loss of function in the first temporal and angular convolutions and the intervening cortex, seemed justifiable in view of the existence of a cardiac obstruction at the aortic valve, and in view of the post-mortem findings in similar cases in the brain.

During the following months he improved slowly but steadily, the irregular cardiac action being corrected by the use of digitalis. He soon recovered the power to name objects and to write after a copy, but was still unable, in July, to write at dictation or to add and divide. His wife thought that he understood many things he heard, but she admitted that he did not comprehend what he read, for he had given up reading his Bible on this account. It was evident that he understood much that was said to him. Thus it became possible to test his visual field, which was found to be intact on all sides though slightly contracted in the right eye. Ophthalmoscopical appearances were normal from the first.

In October he was very much better. He now understood what was said to him, if it was said slowly, but it was difficult for him to follow conversation, as the change from one topic to another confused him. He would go on talking on a previous subject even when questions on a new one were asked, and his wife says that she has to indicate to him that the subject is changed by clapping her hands. He is able to name objects quickly and correctly and speech is as fluent as ever. He reads without hesitation aloud and says that he understands. His wife says that he now reads the papers and tells her the news. So she is sure that he does understand what he reads if he reads very slowly. Rapid reading, like rapid speaking, he is still unable to follow, and for this reason he cannot yet go to church.

His writing is still imperfect. He figures and calculates perfectly, but makes mistakes in writing at dictation and in copying. During an attempt to write he stopped and said, "I can't think how that letter looks." It was a capital H which he wanted; and a little later in the test, when a word beginning with it was given him to copy, he failed to make it properly, writing Nurrison for Harrison. And it is this lack of memory of the appearance of words which prevents his writing with any freedom. There is therefore still a moderate degree of sensory aphasia, the word-blindness being now more prominent than the word-deafness.

Case II. *Word-deafness and word-blindness; temporary apraxia.*—T. D. C——, aged forty-two, right-handed, suddenly became unconscious on March 11, 1888, and on coming to himself a few minutes later felt bewildered, did not recognize his surroundings or his wife or father, and could not talk intelligibly or understand what was said to him. He therefore presented symptoms of aphasia with psychical blindness. His alarm led him to desire to see his physician, Dr. Walker, to whom he at once wrote the following note, which he apparently read over after it was written and sent off with the idea that it was a request for an immediate call. The note is written in his natural handwriting and reads: "Please person me personally per me Dr. personally me personally me. My love. T. D. C." Dr. Walker saw him on the following day and found a condition of almost total aphasia. He tried to talk, but could not be understood, the words used being disconnected. He said, "Crazy, I am crazy!" and he was unable to reply to questions, as he could not understand anything said to him. He was slightly paralyzed on the right side of the face, not elsewhere, and he had pain over the left eye and in the forehead and head on the left side. For a week this condition remained and then he began to improve rapidly, recognized his family and friends, regained the use of words, and on March 24th wrote a letter of some length quite correctly to Dr. Walker. I saw him March 25th. He then talked freely and rapidly, so that no one would have noticed any difficulty of speech, articulation being distinct and words used correctly. He was able to write spontaneously freely, but has difficulty in writing at dictation and in copying. The words dictated had to be repeated if more than three words were given, and in copying he scanned closely each letter and word. But writing thus slowly he made no mistake. There was, therefore, no motor aphasia or agraphia.

There was, however, marked impairment in his power of understanding what he heard or read. My questions were only understood when spoken very slowly and repeated, and any sudden change of subject caused evident bewilderment. His wife had found it very difficult to make him understand, and as she spoke to him in French it was evident that this, as well as his English memory of words, was impaired. He had been to the theatre and occupied a front seat the day before I saw him, but had been unable to understand the words of the play, so that, as he said, "The actors might as well have spoken in Greek." Unfamiliar words were not as readily understood as common ones, and the bewilderment increased as he was examined; so that at the end of half an hour he did not understand as quickly as at first. He was able to repeat single words after me, but if more than two or three were given him at a time he failed, and in a long phrase only occasional words were remembered. His recollection of familiar sentences, *e.g.*, "Peter piper," was, however, good. The same trouble was noticed in writing at dictation as in repetition. He recalled the name of various objects shown to him readily. He therefore had partial word-deafness.

When asked to read he did so to himself and aloud accurately. But he only understood short sentences, and if long ones were read through they conveyed no idea to him. He was spending most of the time in reading, but confessed that he only got an indefinite idea of what he read. The single words, if dwelt upon long enough, are understood, but when combined into sentences are not fully comprehended. He remembers having read the note to Dr. Walker, and supposed it was written correctly. When given paragraphs of a newspaper to read he was never able to tell subsequently the contents of the paragraph when he had read it rapidly. In writing from a copy he could only recollect the appearance of a word or two of the copy and had to consult it frequently. There was therefore partial word-blindness.

Hearing and sight were perfect, the visual field being equally extensive in both eyes and normal. No trace of the psychical blindness remains. He has a systolic murmur, heard at the apex and conveyed to the back. He did not recover from his sensory aphasia, but went abroad, and died in Paris of acute encephalitis about the middle of April.

In both of these cases the power to speak, the power to write spontaneously, the power to read aloud were preserved; the power to understand spoken or printed language was lost, and the power to repeat sentences, to write at dictation, or to copy was impaired. In both, the power to recall the names of objects seen was much better than the power of recognizing those names when heard. In both, the things which were read aloud correctly were nevertheless not comprehended. In both, the condition present was pure sensory aphasia without any affection of articulation, or of the use of the pen; and in both a very marked degree of recovery had followed the attack. In both, the word-deafness and word-blindness were about equally marked. In neither was motion, sensation, sight, or hearing markedly impaired.

CASE III. *Paraphasia progressing to total aphasia.*—H. A. T——, aged fifty-four, right-handed, after a severe mental strain gradually developed a difficulty of speech during a period of three weeks preceding the time when I saw him in consultation with Dr. O'Dwyer on January 9, 1885. He first misplaced words, using one word when he meant to use another, both in speech and in writing, and this increased until his speech became almost unintelligible. At the same time mental failure was thought to be present, as he seemed less able to understand what was said to him than formerly, and had forgotten many words and names. On examination it was found that he understood fairly well all words and short sentences, but failed to follow long sentences or complex orders. When told to walk, to stand still, etc., he did so; but when told to pick up a pack of cards and put them on another table he did not catch the idea till it was repeated slowly. His power to recall the names of objects was very much impaired, but he dissented from wrong names and recognized the right names when told. He often recognized the fact that he had not said the word which he meant to say, but he did not succeed in this always; so that he often became indignant with his wife because she failed to understand him. He could not recall the names of presidential candidates, of the day of the week, or month; and even when told he forgot them at once. There was, therefore, considerable auditory amnesia and word-deafness. There was also some word-blindness. He read single words, but sentences seemed to convey no idea. When he attempted to read aloud he uttered jargon. When he attempted to write, either voluntarily or at dictation, or after a copy, he only succeeded in making a series of badly-formed letters, few words being properly spelled and the result being illegible. Though an expert accountant he failed to add or subtract correctly, putting down and saying out loud the wrong figures every time. That his mental powers were not impaired was evident from the fact that he would not allow me to take the paper on which these attempts at writing had been made until I tore off and gave to him the part containing his name. There was evidently a considerable degree of word-blindness.

His power of articulation was good, words being well pronounced and his speech rapid and fluent. Like the power of handling the pen, the power of forming words was unimpaired. There was no motor aphasia and no motor agraphia.

But the chief defect consisted in a substitution of some word for the one which he wished to use. Thus when asked to name the card of a pack with which he had been playing he called the four of spades "five of telephone;" "trying to do" he pronounced "trayling to dool." His alphabet was said as follows: "a, m, w, x, w, m, x, y, w," the constant recurrence to "m" and "w" being noticed; he also substituted m for four in counting from one to ten. The The days of the week were not said correctly, Friday coming next to Tuesday, but this he noticed and corrected after saying them all over from the first. He made mistakes in repeating words after me, as well as in talking and in reading aloud. This difficulty of speech becomes worse when he is excited, and then not a single sentence of a long harangue can be comprehended. This is especially unfortunate, as he is anxious to give directions regarding financial affairs and about his will, and though he knows what he wishes it is impossible for others to learn his desires, either by his speech or in writing.

Vision and hearing good; slight paresis of right side of face and tongue, none elsewhere; no anæsthesia; optic disks normal; no cardiac disease. Syphilis is suspected but no history was obtainable, and specific treatment, on which he was placed, failed to modify the course of the disease, which progressed to total aphasia and right hemiplegia, and he died comatose on February 9, 1885. No autopsy was obtained.

In this case a partial degree of word-deafness and word-blindness was accompanied by a very marked condition of paraphasia with paragraphia.

CASE IV. *Paraphasia and paragraphia.*—W. E. V——, aged forty-five, right-handed, became unconscious suddenly in March, 1884, and on recovering consciousness was unable to talk, had much tingling and numbness in his entire right side, but no paralysis. For a month he could only say, "How many," but then the use of words returned, and improvement has been steady until February, 1885, when I saw him. He is an intelligent physician and interested in his own case. He understands perfectly whatever he hears or reads, and has no evidence of psychical blindness or deafness, though for a few weeks after the attack he could not play cards or enjoy music as he had formerly done. His pronunciation and his power of using the pen are perfect, and his only complaint is that both in speaking and in writing he uses wrong words. In talking he chooses his words carefully and speaks slowly, but makes occasional mistakes; *e.g.*, "when" for "well," "lant" for "lance," "misplate" for "misspell." He says his alphabet, and counts perfectly. He says that, when unable to say the word he is thinking of, if he calls up to his mind the appearance of the word as written he can usually pronounce it correctly; and it is found that he makes fewer mistakes in reading aloud than he does in talking. In writing he often mispells words, *e.g.*, "unforable" for "unfavorable," "sencotts" for "senate," but he copies freely, remembering several words easily, and he writes well at dictation. He says that he has sometimes written the name of one drug in a prescription for another, and that he is also apt to write the quantities wrong, so that he never fails to read his prescriptions several times. He finds much difficulty in keeping accounts, addition and subtraction being very much impaired, and the results being very apt to be wrong. The condition is therefore one of paraphasia with paragraphia. He has cardiac disease, which makes it probable that the lesion is embolic in origin. Vision and hearing unimpaired. Six months subsequently a slight improvement had taken place, but he never recovered entirely, and died of cerebral embolism three years later.

Such an uncomplicated condition of paraphasia is rare, and it is especially interesting to notice that conduction of impulses from the word-hearing centre to the word-uttering centre was more interfered with than from the word-seeing centre to the word-uttering centre. He therefore got over the obstacle by calling to mind the appearance of the word, and then could say it when the recollection of its sound was insufficient to initiate the movement. The lesion therefore affected the association-tract between the temporal and frontal lobes more seriously than the one between the angular gyrus and the frontal lobe.

RENAL CANCER WITHOUT URINARY SYMPTOMS.—Dr. Julius Wesselowski reports (*Medical Register*) a case of cancer of the kidney occurring in a child aged five years—female. At the autopsy the left kidney was found the seat of trouble, it weighing two pounds and eight ounces. There was found neither albumin, blood, nor pus in the urine during life. The pain was severe, and there was icterus due to pressure on the ductus communis choledechus.

THE ASEPTIC USE OF MALGAIGNE'S HOOKS IN TRANSVERSE FRACTURE OF THE PATELLA.

By J. WILLIAM WHITE, M.D.,

SURGEON TO THE PHILADELPHIA AND GERMAN HOSPITALS, ASSISTANT SURGEON TO THE UNIVERSITY HOSPITAL, ETC.

A. B——, aged thirty, was admitted to the German Hospital in April, 1888. The evening previous, in alighting from a train which had slowed up, but was still in motion, he had made a violent effort to preserve his balance, had felt something give way at the front of the right knee, and had suddenly become unable to use the limb. When examined, twelve hours later, the circumference of the right knee was twenty-one inches as compared with fifteen and a half inches on the left side. There were considerable tension and marked fluctuation. The fragments of the fractured patella were indistinctly felt, separated from each other by an interval of about three inches. He was in considerable pain, and was quite unable to extend the limb. After thorough and scrupulous purification of the skin about the joint I proceeded as follows: A hollow needle was introduced, first to the inner and then to the outer side of the swollen joint, and several ounces of bloody fluid were withdrawn by aspiration. This enabled the fragments to be readily palpated and brought into good position. The apertures made by the aspirating needle being then closed with iodoform and collodion, two pairs of Malgaigne's hooks, which had been previously boiled and soaked in a one to twenty solution of carbolic acid, were placed *in situ*, the upper hooks of each pair being fastened firmly in the edge of the upper fragment close to the insertion of the quadriceps tendon, this being drawn downward. The other hooks were placed in position by being thrust through the soft parts into the inferior edge of the lower fragment. On approximating them, by means of the screw, the fragments of patella were brought apparently into almost perfect position, the line of fracture being barely discoverable, by reason of a slight elevation of the lower edge of the upper fragment. This procedure was effected under antiseptic irrigation, and the limb was then dressed by encircling the joint with moist sublimate gauze, which included and covered in the hooks; outside of this a layer of sublimate cotton was placed, and the limb was carefully bandaged with an antiseptic roller. It was then placed upon a posterior splint, and the foot elevated for about eighteen inches. The patient had absolutely no symptoms whatever. There was no elevation of temperature, and on the two occasions when the joint was looked at the fragments were found to be in the same excellent position, the injured knee had the same appearance as the opposite knee, and the hooks did not even produce the ulceration of the skin or soft parts which I had anticipated. At the end of five weeks the hooks were withdrawn by easing the points out, first from the lower and then from the upper fragment. This was readily done without disturbance of the broken bone, and an examination then made by my colleagues and myself established the fact that the fragments were in close contact, and that it was barely possible to discover the line of fracture. The limb was again placed upon the posterior splint, the little apertures left after the removal of the hooks were dressed antiseptically, and the patient left undisturbed for some days. The splint was then removed, and a figure of eight bandage placed around the joint. The patient moved and tossed around in bed, but, so far as I could learn, did not get out or make any attempt to use the limb for support or progression. I was about to order slight passive motion, when another examination revealed the fact that a slight separation of the fragments had occurred to the extent, possibly, of three-eighths of an inch. The posterior splint and figure of eight bandage were at once reapplied, and the question submitted to the patient of the propriety of cutting down and wiring the patella. He declined the operation, and left the hospital some weeks later with a fairly useful limb, the fragments having undergone no further separation.

The proper treatment of fracture of the patella is at the present day still a subject of disagreement among surgeons of experience and ability. The questions to be considered in arriving at a definite conclusion as to the merits of the radical method of cutting down and wiring the fragments are as follows:

1. Are the results obtained by the ordinary methods of treatment satisfactory?
2. If not, what are the causes of failure?
3. Is there no method less radical than that of opening the joint and wiring the fragments which will be equally effective?
4. If the latter be answered in the negative, what are the dangers of the operation of wiring?

Taking these questions up in the order mentioned, there can be little difficulty in answering the first one in the negative. Every surgeon is familiar with the disability accompanying ligamentous union in cases of transverse fracture of the patella, and it is safe to say that bony union is one of the rarest occurrences after such an injury. The patient, with a fibrous band of an inch or more in length interposed between the upper and lower segments of his patella, will have a gait which is peculiar and unmistakable. He cannot bring forward the foot without flexing the knee, he cannot go downstairs without placing both feet on the same step at the same time, on account of his inability to maintain the leg of the injured side with any certainty in the line of the thigh. If he is in the supine position he cannot lift the limb while holding the leg in full extension. In addition, there is a feeling of uncertainty in standing and walking, frequent and recurrent hydrops articuli, atrophy of the quadriceps femoris, often more or less joint-pain, in many cases the necessity for a brace or knee-cap, and other minor inconveniences. Refracture is not uncommon, and in the very best cases convalescence is tedious and protracted. These conditions are not exaggerated. While Malgaigne states that he has never seen the function of the limb completely restored even when the separation was limited to one-third of an inch, Dennis asserts that after a careful analysis of a large number of cases treated by the older methods he has found that a separation of the fragments amounting to half an inch is considered a most favorable result.

It is evident, without further argument, that as compared with this condition a close bony union of the fragments is greatly to be desired. Mr. Henry Morris has, to be sure, called attention to the fact that in cases where the fibrous band is very short and firm there is practically no weakening of the joint, and that in such cases, when refracture occurs, it is the bone and not the ligamentous band that breaks. Even admitting these statements as correct, I am convinced, after an independent investigation of the subject, that such results as Mr. Morris describes are extremely rare, and cannot be confidently expected in more than five per cent. of ordinary cases.

2. The alleged causes of failure to procure better results by ordinary methods may be divided into three classes.

a. Mr. Lister believed that non-union was usually due to two factors: The separation of the fragments by the contraction of the quadriceps muscle, and the presence of accumulated fluid within the joint. *b.* Von Bergmann thinks that the atrophy of the quadriceps, due to the pressure of the dressings employed and to disuse, is progressive, and believes that this condition is responsible for a large proportion of the cases in which it is impossible to extend the limb. *c.* Macewen believes that the chief cause of non-osseous union is the interposition of fibrous and aponeurotic structures between the fractured surfaces, and that, before such union can be obtained, it is requisite in the first instance to elevate all the tissues which lie over the fractured surfaces and which prevent them from coming into intimate contact. In explanation of this view he details cases in which he has found portions of the soft parts lying between the fragments, either forced there by the vulnerating body in cases of direct injury, or driven in by atmospheric pressure when the fracture is the result of muscular violence. In such cases the fibrous and aponeurotic structures, being more elastic than bone, the latter breaks first and then retracts, while the soft parts stretch, give way, and are then forced in between the fragments by the pressure of the outside air. Macewen's observations have been corroborated by Hardy, Laylard, and others. Fowler, of New York, reported a case in which he found irregular, shreddy fibres of the soft tissues at the upper edge of the rent intimately adherent to the projecting spiculæ of the roughened fractured surface of the upper fragment. Sir Joseph Lister has recently told me that, in his own cases of fractured patella, he had frequently found it necessary to elevate such portions of the soft tissues from between the fragments, and he expressed a general acquiescence in the view which attributes to them the chief importance in the production of ununited fracture.

It is safe to say that the above-named causes include all the chief factors which tend to produce non-union; but much depends upon the relative importance which is assigned to them. It is self-evident that continued separation of the fragments must prevent union by bone. It is almost equally probable that a large unabsorbed or organized effusion of bloody synovia will have the same effect. Atrophy of the quadriceps will, of course, and necessarily, interfere with the further use of the limb and would serve to increase the disability apparently due to the want of bony union. As to the influence of fragments of soft parts interposed between the bones, it would seem, on *a priori* grounds, to be the least potent factor of the three, as absorption and disappearance of soft and living tissues under such circumstances might reasonably be expected.

One of the strongest advocates of wiring adopts the plan of turning the ends of the wire in between the bones instead of hammering them into their outside surface. This would seem to offer an obstacle to bony union at least equal to that caused by the presence of shreds of fibrous tissue; but it did not seem to affect his results, which were excellent. It is evident that if Macewen's explanation be the correct one, and the interposition of the prepatellar fibrous structures be the chief cause of non-union, the only rational method of procuring bony union is by cutting down and elevating these fragments of the soft parts. The other indications can, however, be met by much simpler and safer methods of treatment The exudation in the joint can be removed by aspiration. The fragments can be brought together and held in position by bandages, or by Malgaigne's hooks, as in the case above described. Indeed, immediate aspiration of the joint and the aseptic application of Malgaigne's hooks covered by sterilized or aseptic dressings, together with the use of a posterior splint and a light, moderately firm bandage, would seem to meet every indication except the one which has been mentioned. The use of the hooks enables us to dispense with the excessive pressure by bandages or otherwise required to keep the fragments in apposition. It certainly approximates them more nearly and accurately than does any other method I have ever seen, with the exception of wiring. It combines all the advantages of the old methods by splints and plaster with a greater degree of accuracy in bringing and holding the fragments together. There should be scarcely more risk of septic infection than in an ordinary subcutaneous tenotomy, provided ordinary care as to aseptic precautions be taken at the time the hooks are introduced. If Macewen is mistaken in assigning to the influence of the presence of the prepatellar structures the majority of cases of non-union, the aseptic use of Malgaigne's hooks would, in my judgment, be the most rational method of treating transverse fracture of the patella. It must be confessed, however, that the case above described rather seems to corroborate Macewen's theory. I think it quite possible, however, that I removed the hooks two or three weeks too soon; and that their longer retention might have resulted in a permanent bond of bony union.

In estimating the comparative value of the different methods, it is needless to say that the danger to life should exert a predominant influence. This danger is undoubtedly greater by the method of wiring than by any other plan of treatment. And it is this fact which causes careful surgeons to hesitate to-day in recommending its employment. Of the 186 cases included in the table of Dennis, there were 34 cases of suppuration, 4 amputations, 24 cases in which the result was said to be poor, 14 of them were said to be complete anchylosis, and there were 11 cases which terminated fatally. Of the remainder, 35 were marked as ending with a fair result, 17 of them having incomplete or partial anchylosis. Mr. Lister himself has told us that before he made the incision in the first case of wiring which he ever performed, he remarked to those sitting around him in the amphitheatre that he considered no man justified in performing such an operation unless he could say with a clear conscience that he considered himself morally certain of avoiding the entrance of any septic mischief into the wound.

The opposition at this time (November, 1883) was very strong, and such surgeons as Mr. Bryant, Mr. Adams, Mr. Sidney Jones, Mr. Henry Morris, Mr. Edmund Owen, and Mr. Grant placed themselves on record as opposed to the operation, believing that the bulk of simple fractures do well enough without it, Mr. Christopher Heath going so far as to remark that he thought Mr. Lister's paper would cost many knees and many lives. As recently as August, 1887, we find that Messrs. Barker, Thompson, Stoker, and Robson were equally opposed to the indiscriminate performance of the operation. The strength of the feeling against the operation, only a few years ago, is well shown by the following conclusions reached editorially by the London *Lancet*, after a full consideration of the subject. They were:

1. That the operation is not suitable as a primary measure; 2. That in view of all its dangers and of the good results obtained by other and perfectly safe methods of treatment, it is not commendable for general employment; 3. It is not justifiable unless with most absolute asepsis.

The French Academy of Surgery pronounced against it with almost equal force, and the most recent writers on fractures and dislocations have freely agreed with Pick, who says that he would not permit the operation to be done upon himself, and therefore cannot recommend it to his patients.

Mr. Howard Marsh (Art., "Fracture of the Patella," Heath's "Dictionary of Practical Surgery") says that the prevailing opinion in regard to this operation is that in cases of recent fracture it is uncalled for, while in many cases of old fracture it is impossible to carry it out in a satisfactory manner. He adds that he cannot recommend Malgaigne's hooks, as their use has been followed by diffuse inflammation around the patella, and even by suppuration of the knee joint, ending in some cases fatally, in others in anchylosis, and because, although they draw the fragments more closely together than any other method except wiring, they do not by any means insure bony union. Packard (Article on "Injuries of the Bones," "International Cyclopædia of Surgery," vol. iv.) only countenances resection and suturing when everything else has failed, and it is clear that want of union between the fragments is the sole cause of the disability. Ceci (*Deutsch. Zeitsch. für Chirurg.*, February, 1888) describes a method consisting of a subcutaneous buried suture which surrounds the patella, and passes through the tendons above and below it close to its margin. He reports 5 cases in detail, all of which were successful. He believes that this plan of treatment has the following advantages: The general applicability of the suture, no matter how great the comminution of the patella; the mechanical union of the fragments, independent of new bone-formation, and affording sufficient and permanent resistance to the disjunctive forces; the subcutaneous character of the entire operation, permitting of rapid and thorough repair of the superficial and deep soft parts, completed in his cases in from four to eight days; the removal of the splints as early as the end of the first week, after which the joint requires neither immobilization nor compression. The practical advantages of the method he thinks may also be seen when it is studied in its relation to the causes of non-union. If, for example, union does not take place on account of blood or synovial exudation, puncture of the joint or aspiration is not required, as the exudation will escape through the openings made to admit the suture, and this emptying the joint can be facilitated by the employment of gentle massage. Atrophy of the quadriceps is to a great extent avoided, by the very early period at which passive motion or even active movement can be permitted. If union is prevented by the interposition of fibrous bands, the subcutaneous wire suture is sufficiently strong to hold the fragments together.

In several of his cases, months afterward, the wires could be felt plainly through the skin and gave rise to no trouble or inconvenience of any sort. The operation appears to bear a close resemblance to that of Volkmann, who employed a silk suture passing out through the quadriceps tendon and through the tendo-patellæ, and to that of Kocher, who passed a silk thread above and below the fragments by means of a transverse or longitudinal incision. König has done a similar operation, employing catgut. I have have had no opportunity of testing this operation practically, but it would seem to be open to the same criticism as the use of Malgaigne's hooks; that is, if bony union is the object aimed at by the surgeon in the treatment of this fracture and if such union is prevented by the presence of fibrous tissue between the fractured surfaces, the encircling wire, while it insures approximation, as do the hooks, will yet fail to bring about osseous repair. It is hard to believe that, in the absence of such union, the wire will permanently hold in place the fragments of a broken patella. It would appear that the methods by buried sutures were at least open to the same objections as the use of the hooks, namely, the risk of consecutive inflammation and suppuration. Cases of this kind have already been reported by Agnew, Hamilton, Volkmann, and others, but in the majority with which I am familiar the hooks were used with little or no antiseptic precaution.

It appears to me that, in connection with this subject, the most important practical point now before the profession for final and conclusive settlement by means of large numbers of carefully observed and recorded cases is that which relates to Macewen's theory of the cause of non-union. This applies to all recent fractures, and in each case which is operated upon by incision and wiring, in all cases of compound fracture of the patella, and in all instances in which patellar fracture is associated with other and fatal injuries and in which an autopsy is attainable, the condition as to the presence or absence of prepatellar fibrous tissue between the fragments should be carefully observed and noted. In old fractures of the patella with marked disability, especially when that disability results from wide separation of the fragments, there is a general concurrence of opinion to the effect that wiring is justifiable. Mr. Lister, however, at the time of his original address upon this subject said that he considered the old ununited cases as in every respect worse subjects for operation than the recent ones. There is certainly one difficulty—that experienced in approximating the fragments—which does not exist in cases of recent fracture. Mr. Turner has reported a case in which the difficulty of bringing the fragments together caused the abandonment of the operation. Mr. W. E. Ward has recorded one in which the wires repeatedly broke during an attempt to bring together the fragments in a fracture five months old.

In these cases Malgaigne's hooks were used and left in for thirty days, the wound and the hooks together being enveloped in a salicylic and iodoform dressing. J. E. Michael and Muskett have each reported cases in which it was impossible to bring about accurate apposition of the fragments. Tenotomy and myotomy of the quadriceps have been resorted to to overcome this difficulty. Macewen has recommended a series of **V**-shaped incisions made into the substance of the muscle, as a means of lengthening it without much diminution of its strength. Cameron, of Glasgow, first frees the under-surface of the muscle from the bone by means of a blunt instrument introduced beneath the upper fragment of the patella, and then incises the muscle itself obliquely at two places, the cuts beginning at the inner and outer edges a short distance above the patella and running parallel with each other nearly to the opposite edge. They go through the entire thickness of the muscle and permit of great elongation without complete severance of its continuity. Lister now uses this method in old cases attended with shortening.

In 22 recent cases of wiring, Turner reported no deaths and one case of anchylosis, while in 28 old fractures which were wired there were 2 deaths and 7 cases of anchylosis. I believe that, with our present knowledge of the subject, the following conclusions are justifiable :

1. The results obtained in transverse fracture of the patella by means of splints, plaster dressings, or bandages are extremely unsatisfactory, owing chiefly to the absence of bony union, to the length of the fibrous band interposed between the fragments, and to the accompanying atrophy of the quadriceps muscle.

2. If further observation shows that the chief difficulty in getting good union lies in the separation of the fragments and the presence of blood and synovia, the treatment to be preferred will probably be some form of the prepatellar wire suture or the aseptic use of Malgaigne's hooks after aspiration of the joint.

3. If, however, as seems highly probable, the chief cause of non-union is found to be the presence between the fragments of portions of the aponeurotic tissue in front of the joint, it will be good surgery in all cases of recent fracture to cut down with the strictest and fullest antiseptic precautions and wire the fragments.

4. In old fractures, on account of the increased risk and the difficulty of the operation, the disability of the patient should be quite decided before wiring is recommended by the surgeon.

SALICYLATE OF MERCURY IN VENEREAL DISEASES.—After a number of experiments with this drug, Dr. Szadek comes to the following conclusions : 1. Salicylate of mercury is as efficacious a remedy for syphilis as any other mercurial employed until now ; it is most suitable for application in secondary affections ; given internally, it causes the milder symptoms of syphilis to disappear. When introduced into the organism by deep injections, it quickly removes all symptoms of syphilis. 2. Given by the mouth, or by means of deep injections, it does not produce any injurious effects, and in this regard it differs from other mercurial preparations, and may be employed as the most suitable mercurial in syphilis. 3. Employed externally, it is very useful in various local syphilitic affections, producing resorption of gummata and healing up primary and secondary ulcers. 4. In acute and subacute gonorrhœa it produces no abortive action on the course of the disease ; in some cases, however, it acts well, causing a diminution in the discharge.—*Przeglad Lakarski*, June 9, 1888.

GLYCERINE OF STARCH AS A SURGICAL DRESSING is highly recommended by Dr. Charles E. S. Flemming. He dissolves in the glycerine some antiseptic like the bichloride.

A NEW METHOD OF STUDYING THE PECULIARITIES OF COLOR IN SKIN DISEASES.

By FREDERICK J. LEVISEUR, M.D.,
NEW YORK.

THERE is no doubt that color, as a symptom, plays a very important rôle in the diagnosis of skin diseases. Yet we have no sufficient facilities at our disposal to study this symptom more closely. A glance at the descriptions of skin eruptions in text books and medical journals will invariably impress one with the fact that a more general understanding of the peculiarities of color in diseases of the skin is very much called for. Bluish or yellowish red, deep or pale red, red shading to yellow, copper, or tan-colored, red with a violaceous hue, even irritated or (*horribile dictu!*) angry-looking, are some of the terms with which we are often confronted. These certainly are devoid of meaning, and to hurl them at the inexperienced student recalls to mind the futile attempt of describing the colors of the rainbow to a man born blind. During my stay at the Hôpital St. Louis, Paris, I made a careful study of the large collection of wax models representing skin diseases. Monsieur Baretta, the renowned maker of these models, keeps the details of the manufacturing process strictly secret, and very little could be learned from him about it. On investigating the subject, I came across an article by Dr. Brooke, of Manchester, in which the writer, in a very clear manner, gives an able description of "The Plastic Representation of Skin Diseases" (Dr. Unna's *Monatshefte fuer praktische Dermatologie*, 1885). This article, and the material placed at my disposal through the kindness of Dr. L. D. Bulkley, of the New York Hospital, enabled me to pursue my work. It is my object to demonstrate, in the course of this article, that to produce good models no "mighty magic" will be called into play on the part of the operator, but only a little dexterity, which anyone can easily acquire. It is hoped that other colleagues may be induced to begin work in plastic representations, for it offers a novel, yet the most reliable, method of fixing in mind and studying the transitory manifestations of skin diseases.

The following is a *résumé* of the manner of producing wax models of parts of the body and extremities. To model parts of the face or limbs in their entirety is a more complicated process, which requires some experience and is easier to be demonstrated than described.

The first step is to take a plaster-of-Paris cast of the seat of the disease. A good-sized porcelain bowl is partially filled with cold water, into which plaster-of-Paris powder is sifted without stirring. The plaster of Paris used by dentists is the best, especially if it has been kept carefully dry and is not flabby. As soon as the water ceases to readily absorb the plaster of Paris, dip the hand into the mixture directly underneath the surface of the liquid and gently keep stirring the latter, always carefully avoiding the production of air-bubbles. The pap will then soon begin to thicken. Now pick it up with a scoop, and gradually pour it upon the part to be modelled, the latter having previously been prepared in the following manner : First, it is carefully cleansed, dried, and lightly painted over with oil by aid of a fine camel's-hair brush, and then surrounded with a projecting wall of moulding, clay, or wax, in order to prevent the plaster-of-Paris mixture from spreading, and cause it to cover the object in a layer thick enough to guarantee a solid and durable cast. Besides, all the cavities and recesses due to the roundness of the human body are filled with the same material. We avoid thereby a good deal of trouble afterward, when it comes to taking the cast off the patient's body. We return now to the plaster-of-Paris mixture which was ready for use, and pour a large quantity of it upon the cast which has been prepared in the manner just described. Ten to fifteen minutes will elapse before the pap becomes sufficiently hard to be taken off. In removing the cast from the patient we proceed very carefully, lest we break or crack it. It is advisable to gently loosen the edges of the cast with a blunt knife and then gradually lift it from the skin. The cast taken off the patient has, on its concave side, an exact impression of the part we intend to model. The elevations found on the patient's skin (however minute they may be) form depressions in the plaster-of-Paris cast, and *vice versa.* It is obvious that, by using this cast as a mould or matrix and making a second cast from it, we will get a correct fac-simile of the part of the patient's body with all the details of formation of normal and diseased skin.

The general shape of the plaster-of-Paris, or first cast, as taken from the body, resembles a trough or gutter, and in order to make it serve the purpose of a mould, it is necessary to build a sort of wall of plaster of Paris at those sides which, when left open, would let run out the prepared material about to be described. We intend to use this mould like a pudding-form or pan, and have to take care to remove all the prominent edges and projecting points in order that our second cast, *i.e.*, the wax model, will slip out of the mould with the same ease as a pudding does. After this has been accomplished, the mould is immersed in water, which it readily absorbs, owing to the porosity of the hardened plaster of Paris. When it is thoroughly wet it is taken out of the water, emptied, and freed from drops which are likely to collect in the recesses by blotting-paper. It is then ready for use, and we may proceed to prepare the wax mixture and cast the model. Three hundred parts of white wax, together with ten parts of paraffine, are melted over a sand-bath in a porcelain pot with a wooden handle and a broad nozzle. A good mixture of two hundred parts of finely powdered talcum and one hundred parts of amylum is then strewed into it, with continual stirring. A yellowish-white, thick but fusible, mass is the result. By adding a few drops of an alcoholic solution of carmine we give this wax mixture a light-pink color, and then rapidly pour it into the wet plaster-of-Paris mould, filling the latter to the brim. We now let it alone for about ten minutes, after which we pour three-fourths of the contents of the mould back into the pot. By shaking the mould the remaining wax mixture is found to spread itself in every direction. As it cools it becomes hard and forms a hollow cast of the plaster-of-Paris mould. We finally turn over the mould and let the wax cast, *i.e.*, the model, slip out of it by its own weight.

The mounting of the model is accomplished after the following fashion. Pieces of white mousseline, soaked in liquid glue, are placed all around the borders of the model, and this, in turn (model and surrounding mousseline), is fastened on a thin black-board, kept from warping by two small stretchers. The life-like appearance, the exact color of normal skin of the model, will invariably surprise the operator. He has now to add the pathological changes in color and some other details, and the model is finished.

We have found that we have to deal: 1. With covering colors; 2. With penetrating colors; 3. With effects of colors.

For covering colors we use oil-colors, mixed with oil of turpentine; for penetrating colors, water-colors rubbed up with lanolin (Liebreich). To produce effects of color which are due to a colored stratum of the skin shining through a semi-transparent layer, likewise variously colored, is more difficult, and demands the combining of both penetrating and covering colors. I do not intend to dwell now at full length upon the manner how to color the wax models, but shall do so later, when taking the liberty to give to the profession some notes which I have collected regarding the peculiarities of color in skin diseases.

687 LEXINGTON AVENUE.

WHAT'S IN A NAME?—The Kansas City *Medical Index* requests all contributors to its columns, who may have occasion to refer to antipyrin or antifebrin, to use the words methozine and acetanilide for these drugs respectively, since the former are names of patented articles.

Clinical Department.

A RANULA CAUSED IN A VERY UNUSUAL MANNER.

By WILLIAM FREEMAN FRENCH, M.D.,
NOROTON, CONN.

F. E——, a school-boy, aged eleven, called at my office on September 22, 1888, to have cut out what his teacher called a gum-boil. On questioning him, he said that, one week previous to the visit, while eating a very hard apple, a piece pressed the floor of the buccal cavity on the right side, causing pain, and within a few minutes there appeared a lump which precluded any further mastication. This lump broke twice during the week, discharged its contents, and then promptly filled again. On inspection I found a tense, semi-transparent, cystic tumor, irregular in shape, about the size of a large walnut, below and to the right of the frænum linguæ, close to the point of exit of Wharton's duct, and the surface had small blood-vessels branching in all directions. The tongue was crowded to one side, and could not be protruded beyond the teeth. Erichson relates a similar case in which a ranula was caused by the slipping of a pair of tooth-forceps, wounding the floor of the mouth near the Whartonian duct, and the collection of fluid accumulated in the cyst was actually submaxillary gland-secretion. Treatment was the passage of a seton through the cyst-wall to evacuate the contents (which was a viscid fluid), and also to cause inflammatory adhesion and obliteration of the sac. Within ten days the parts returned to their normal condition.

PRECAUTIONS AGAINST INFECTION.

By F. B. STEPHENSON, M.D.,
UNITED STATES NAVY.

THE mortality among physicians attending the sufferers from yellow fever in Florida causes me to think that the following suggestions may be of use:

1. Avoid all unnecessary exposure.
2. Stand rather than sit beside the patient's bed, and remain as much as possible near the bottom rather than the head of the bed.
3. Keep a little off for a few seconds when the bed-clothes are turned down.
4. If near-sighted, draw the breath and hold it hard before looking at the tongue, or narrowly at any other part of the patient.
5. Never stethoscopize unless it be absolutely necessary; when necessary, expose the patient's chest for a few seconds before beginning, hold the breath on a full inspiration while making the examination, and be quick about it.
6. After finishing with one patient, go into the middle of the ward for a few seconds to draw your breath a bit before beginning with another.
7. Never enter a fever ward in the morning without breakfasting, or, if at a too early hour for that, without taking coffee.
8. Have a ward coat, to be cast off and ventilated after getting into quarters.
9. Enforce regular ventilation.

The chief merits of these rules are that they are obvious in their object, easily acquired so as to become a habit, and such as may be practised without exciting any attention from by-standers.

These precepts, though formulated for hospital service by a scientific practitioner of a past generation, appear adaptable to the daily life of medical men in private practice.

A CASE OF OBSTRUCTION OF THE BOWEL; ONE THOUSAND WATERMELON SEEDS REMOVED FROM THE ANUS.

Dr. W. Z. Holliday, of Harlem, Ga., writes: "A few days ago I was called to see J. M ——, negro. Inquiring as to the nature of his trouble, he stated that he was 'clogged with watermelon seeds.' He ate heartily of melons on Wednesday night, and since that night has had pains and straining in his bowels, with continuous desire to go to stool, but was unable to evacuate his bowels. Digital examination per anum confirms his diagnosis, and he is found very much 'clogged.' I can introduce my finger only through the sphincter; then the resistance of a solid mass of seeds prevents its further admittance. After getting a little opening by pulling away the seeds just inside the sphincter ani, I gave him a copious enema of tobacco-infusion. This soon had the desired effect, and he was *thoroughly relaxed.* After this I could easily remove the mass, which was very tightly impacted. The rectum, and perhaps part of the colon, was filled with this foreign material. It was with much difficulty that I reached in far enough to get it all; however, the contractions of the bowel would force the mass down as it was removed from below. Having gotten away all I could reach, and being quite sure most of it was out, I proceeded to count the seeds, and found there were just eight hundred and twenty. His wife now assures me that she had gotten away at least two hundred before I was summoned. So it is a fair estimate to say that the obstruction was originally a mass of a thousand watermelon seeds. He says his bowels are now easy, and that he feels very well. I ordered for him three ounces of castor-oil, to be taken at once, and leave him. Returning next day he says his bowels acted three or four times from the oil, and he is now all right."

A CASE OF RECOVERY FROM TRAUMATIC TETANUS.

Dr. F. B. Streeter, of Glenn's Falls, N. Y., writes: "After having seen several deaths from traumatic tetanus I have the pleasure to report one recovery. On December 13, 1887, I was called to see H——, a farmer's son, aged twenty, who had driven a nail through the thin sole of an old rubber boot into his foot while in the act of jumping. The accident had occurred ten days prior to my visit. The foot was still swollen and tender and the tetanus was well marked, the patient being unable to protrude his tongue or to take any food except fluids. Poultices were applied to the foot, and potassium bromide, gr. xx., was given every two hours. The symptoms steadily increased in severity for three days, and the case seemed hopeless until, at the expiration of that time, an abscess pointed on the back of the foot between the first and second metatarsal bones. This abscess, on evacuation, was found to contain foul-smelling pus and a piece of rubber, which had evidently been carried into the wound by the nail-point, its circumference being about the same. The wound was dressed antiseptically and the patient almost immediately began to recover, and after several months slowly regained his former strength. Without presuming to advance any theory as to the nature of tetanus, or its etiology, I am satisfied that the potassium bromide exerted very little influence for recovery in this case; and in my opinion the thorough opening, cleansing, and disinfection of wounds of this character will afford far more satisfactory results than any course of internal medication whatever."

Treatment of Venereal Warts.—Equal parts of burnt-alum and tannin sprinkled in powder upon venereal warts will desiccate them, and they can be rubbed off in a few days.—*Canada Medical Record.*

Progress of Medical Science.

Supra pubic Cystotomy.—Observations, made during experiments on intestinal suture, in 1881, showing the ready repair of accidental wounds of the bladder, led Professor Rydygier, of Krakow, to the idea, whether the tendency to adhesion of the peritoneum could be applied for cystotomy. To prove this he made a series of experiments on dogs, and encouraged by the results, he operated on a boy thirteen years of age. Rydygier's method of operating is briefly as follows: The patient is prepared as for laparotomy, a catheter is passed into the bladder, and the latter is washed out with a warm solution of boric or salicylic acid, and then partly filled with the same solution. A section is made on the linea alba, as usual. After letting out the solution by means of a catheter, the bladder is drawn out by a silk noose, and iodoform gauze is solidly packed in between the bladder and the edge of the wound. An incision one and a half inch long is made in the bladder, and the finger is inserted and along it the forceps. The bladder is again washed out by the catheter with the above solution, which may overflow the wound of the bladder without entering the cavity of the abdomen. Rydygier recommends applying the furrier's suture according to Czerny's method. This suture has this advantage, that the more the bladder distends the more the suture tightens. It is necessary to keep the catheter in the bladder for eight to twelve days. Rydygier's method can particularly be applied to the entire removal of tumors of the bladder, and it may also be of use in wounds of this viscus. The author concludes his paper by a short recital of his case, in which this method gave excellent results.—*Przeglad Lekarski*, Nos. 6 and 7, 1888.

Multiple Primary Tumors.—The appearance of several malignant tumors of the same anatomical qualities, independent of each other, is not common, and still less frequent, perhaps, is the appearance of many primitive tumors of different character. Two such cases, however, Dr. E. Przewoski, of Warsaw, gives in the *Gazeta Lekarska*, Nos. 19 and 20, 1888. On one patient, when still alive, only one movable tumor, of the size of a fist, was noticed on the neck. This patient came to the hospital complaining of feverishness, pain in the abdomen, and obstinate intestinal obstruction, and died one month after. The post-mortem examination showed cancer of the stomach, and its dissemination on the peritoneum, besides that fibroma lipomatodes in the connective subcutaneous tissue upon the left collar bone, angiomata cavernosa in the liver, knotty fibromata in the kidneys, and psammomata springing from the dura mater. There were, therefore, five different kinds of tumors in different organs. On another person the autopsy showed struma cysticum, angiomata cavernosa in the liver, fibromata in utero, cystic tumor of left ovarium, cancer of rectum, and diffused nævus verrucosus pigmentosus—all together six different tumors. Considering what could be the cause of such extraordinary development of the tumors in the two cases, Dr. Przewoski speaks fully on Conheim's and Rindfleish's theory (the latter admits as the cause of them diminution or want of nervous influence), and does not give his explanation, but leaves the solution of the question to the readers.

Treatment of Pulmonary Phthisis by Parenchymatous Injections of Creasote.—Dr. Teofil Stachiewicz has injected creasote after Rosenbusch's method in the clinic of Dr. Brehmer, in Goebersdorf, and has convinced himself that this method, although it is useful, does not give such results as Rosenbusch asserts. According to the experience of the author, the cough after every injection augments, and the quantity of sputum increases considerably. The author has never seen any influence of injections on the temperature. The action of creasote, according to him, is the same as of any other extraneous body, *i.e.*, the inflammatory action. But as the fluid gets into the affected place, so *in punctu minoris resistentiæ* the inflammation is very destructive, and the quantity of sputum greatly increases. The following are the author's conclusions: 1. If the lungs are affected only on one side and cavities have formed, injecting creasote may produce a rapid destruction of tissue. 2. If the patient is inclined to hemorrhage, the injections are contra-indicated, because every hemorrhage endangers life, and therefore it would be risk to produce it artificially 3. In tubercular infiltrations in which there is obstinate fever with a great number of bacilli, there is danger of the development of miliary tuberculosis. In such cases the injections produce destruction of tissue, and may cause the demarcation of the morbid process. Even in large infiltrations a partial destruction may be occasioned, by which the further invasion of the lungs may be prevented. The author had occasion several times to observe that, with such large infiltrations, even with little destruction after hemorrhage, the morbid process after some time was changed to such a degree that cavities appeared and an improvement quickly followed. For the injections a strong needle, from five to seven centimetres long and one to one and a half millimetre in diameter must be employed, lest a sudden cough break it. After the injection, the patient must lie quiet and an ice-pack is to be applied over the point of injection.—*Przeglad Lekarski*, Nos. 20, 21, 1888.

CANCER OF THE LARYNX.—At a meeting of the French Society of Otology and Laryngology, Dr. Charazac reported an interesting case of cancer of the larynx. The patient, sixty years of age, was in apparently excellent general health, with easy respiration, no cough, no expectoration, a strong-smelling breath, but not fetid. There had been aphonia for the past eighteen months. On examination with the laryngoscope, congestion of the epiglottis and of the left side of the larynx was found, the ordinary symptoms, in fact, of chronic laryngitis. To the right, at the level of the vocal cord, could be seen a grayish ulceration tolerably deep, occupying the centre of a tumefaction which had invaded the ventricular band and which closed the half of the glottis. The author diagnosed the case as cancer of the larynx. The progress of the disease, in spite of the energetic antisyphilitic treatment, confirmed this diagnosis, and on February 19, 1888, tracheotomy became indispensable to prevent asphyxia. Extirpation of the larynx was proposed, but was not accepted by the patient. The author compared the results obtained by palliative tracheotomy with those of extirpation of the larynx in cancer. At first sight, tracheotomy would appear preferable, as it enables the patient to live six or eight months longer, whereas in extirpation of the larynx two thirds of the patients succumb either to the operation or to a rapid recurrence of the affection. But these unfavorable statistics, Dr. Charazac maintained, were due to the fact that surgeons have not always paid sufficient attention to the indications furnished by the state of the patient and the nature of the disease. All cases of cancer of the larynx should not be operated upon. Extirpation ought to be performed only in the case of cancer limited strictly to the interior of the vocal organ, while the general condition of the patient is yet good, and when, as yet, the glands are not affected. Partial extirpation gives better results than those furnished by complete laryngectomy. Whence the necessity of an early diagnosis.—*Revue Mensuelle de Laryngologie*, No. 6, 1888.

NITRO-GLYCERINE IN TINNITUS AURIUM.—Dr. Lautenbach, assistant surgeon to the Pennsylvania Eye and Ear Infirmary, Philadelphia, after a fair trial of nitro-glycerine, has reached the conclusion that it is of value in certain cases of tinnitus aurium—especially in those where cardiac lesion exists, functional or organic, and where there is little or no loss of hearing. In many of these cases more or less structural changes from catarrhal inflammation of the middle ear were present; among them change in the shape and translucency of the drum-head, with accompanying change in appearance or position of the triangular light spot. Follicular pharyngitis was present in some of the cases. The tinnitus was generally constant, or nearly so. It was not, as a rule, more marked when the patient was in a recumbent position; occasionally there was some remission in that position. The thermometric and barometric conditions of the atmosphere influenced the tinnitus; damp weather, with low barometer, usually increased it. Dull, heavy headache, more or less persistent, most frequently parietal, though sometimes frontal, was of frequent occurrence. He used the nitro glycerine in pill form, in doses of one-hundredth of a grain. At first but one pill a day was given, generally in the morning. The dose was then increased, enough being given to diminish the tinnitus or to cause headache. As many as six of these pills were given in a day, though usually two were found to produce a beneficial effect. Improvement sometimes was manifest within a day or two. In cases of long standing, the remedy might have to be continued for one to three months before a satisfactory result was obtained. Cases in which there was recurrence of the tinnitus seemed to yield more readily on resuming the treatment than when the remedy was first administered.—*Philadelphia Medical Times.*

HEMI-CHOREA COMING ON AFTER PARTURITION.—This case was observed at Osler's clinic in Philadelphia. Mrs. X., the mother of three children, had an attack of inflammatory rheumatism, four months after the birth of her last child. From this she recovered, but four months afterward chorea appeared, commencing in the right thumb the twitching extended up the entire arm, and subsequently appeared in the right leg, in which the motion was more marked than in the upper extremity. The choreic movements were confined to the right side. When she applied to the dispensary the above condition was noted; examination of the heart revealed a systolic basic murmur. No valvular lesion was detected. The movements were much worse in damp or stormy weather, so that at times she was not able to walk across her room. She was treated by Fowler's solution, five drops three times daily, and increased until doses of ten or twelve drops were taken, or half a dram daily. An interesting point in the case consisted in the fact that the patient had never had chorea in childhood, and none of her family had been similarly affected.—*Philadelphia Medical Times.*

CYST IN THE HEART.—At a recent meeting of the London Pathological Society (*The Lancet*), Dr. W. B. Hadden brought forward a specimen of cyst in the heart. The patient was a woman of sixty-six, who died of cirrhosis of the liver. There were no symptoms pointing definitely to the condition of the heart, and nothing in the history to explain the origin of the cyst. It was an inch and a half in diameter, globular, thin-walled, and situated in the inter-auricular septum. The contents were pink and grumous, and, microscopically, were found to consist of finely granular fatty material. The walls were of loose, fibrous tissue, and there was no evidence that it was hydatid, dermoid, or serous; its nature and origin were obscure.

METHYLAL INJECTIONS IN DELIRIUM TREMENS.—Kraft-Ebing advocates the use of methylal subcutaneously in delirium tremens. Although large doses are required by the mouth to procure sleep—often as much as sixty grains—administered subcutaneously one and a half grain is sufficient, although two and often six hours are required to bring about the desired result. Earlier investigators, such as Mairet and others, spoke of it as a reliable and not disagreeable hypnotic, but they often resorted to doses of one and a half to two drachms. If Kraft-Ebing's results (restfulness and sleep) after minute doses given subcutaneously prove the rule, it will add materially to the value of the drug.—*The Medical Press.*

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, October 27, 1888.

CALOMEL AS A DIURETIC.

THE observation of Jendrássek that calomel has a powerful diuretic influence has excited wide attention, and led to extensive use of the drug in various dropsical conditions. The fact that calomel has for years been frequently used as a diuretic. in combination with digitalis and squills. or with digitalis alone, is not ignored by the more recent writers. J. Sachs is quoted by Leyden as having long ago used calomel and camphor as a diuretic, and Brafield and Jahn have combined it with iodine in ascites. Among those who have lately reported favorably upon the diuretic action of calomel alone are Mr. Speller Locke ; Dr. Leech. of Lancaster. England ; Dr. Mendelsohn. Drs. Weinstein and Terry, Drs. Talfourd Jones. Leyden, Meyjes, and Schwass.

Dr. Jones contributes an article upon the subject in the *British Medical Journal* of September 22d. He reports a case of cirrhosis of the liver in which calomel seemed to have a practically curative effect. The drug was given in doses of three grains three times a day until he had had five doses. Diuresis set in on the second day, and continued for about five days. Twelve days later a second course of the drug was given, and continued for five days. Diuresis again set in about the second day. At the end of twenty-five days from the beginning of treatment the girth had decreased from forty to thirty-three inches, and dropsy had gone.

Dr. Jones quotes the suggestion of Mr. Locke as to the mode of action of the drug. He observes that it has long been known that the action of squill and digitalis as diuretics is greatly assisted by the addition to them of a little mercury. The part thus played by the mercury has hitherto been never satisfactorily explained, though the recent work of Dr. Noel Paton on the connection between bile-secretion and the formation of urea seems to afford a clew. According to Dr. Paton, the increase of the bile-secretion and of urea is due to the hæmolytic action of the mercury on the blood-cells ; and since. as is well known, an increased quantity of urea in the blood acts as a powerful diuretic, the good effects derived from the use of mercury in combination with squill and digitalis may be explained by its action on the blood-corpuscles.

Mr. Locke, commenting on Jendrássek's paper, thinks the diuretic action of the calomel must be attributed either to the drug containing a trace of persalt or to its being converted to a slight extent into a persalt in the alimentary canal, since Rutherford has shown that calomel causes no increased secretion of bile.

Simultaneously with the appearance of Dr. Jones' article on the value of calomel in cirrhosis, we find one on the same subject by Dr. Schwass (*Berlin. klin. Wochenschrift*, No. 38, 1888), assistant in Senator's clinic. Dr. Schwass states that the warm praise which he gives to the drug in question is based upon two years' experience at the Augusta Hospital. He, however, while commending the use of calomel alone, prefers to give it in combination with digitalis. In this way he was able to give more calomel and keep up its use longer. For example, in one case he gave a grain and a half of calomel, and a grain of digitalis (leaves?) every three hours for a week. It is evident that we here are only getting a revival of the old digitalis, calomel, and squill combination, except that the amount of mercury is increased.

THE COUNTY SOCIETY AND THE WATER-SUPPLY.

IT is quite unfortunate, for the good name of the County Society, that the resolutions offered by Dr. Washburn to rescind its previous indorsement of a private scheme for supplying the city with water were not allowed to pass without question.

The Society cannot afford to put itself upon record as countenancing any private scheme, even under the specious plea of its being for the public welfare. By so doing it loses its influence for good when impartial judgment is expected and opens itself to the suspicion of being led by anyone who may have mere personal ends to serve. It would be well for the members to look carefully into the matter at the next meeting.

A LAY VIEW OF THE MACKENZIE CONTROVERSY.

WHAT the "outside world" thinks of the ever-recurring squabbles and disgraceful disputes of physicians is so well known as to be proverbial. In the case of the late German Emperor, many, if not most, opinions have been formed and expressed on national and political grounds rather than on the clearly understood merits of the case. The Teutonic press, even in our own country, has naturally sided with the German physicians, whereas the Anglo-American journals have taken up the cudgels in behalf of the British specialist.

A noteworthy exception to this rule occurs in a recent issue of the *Illinois Staats Zeitung*, the leading German daily of the West. The German editor of this influential journal openly sides with Mackenzie, for reasons which will appeal to all who have a heart as well as a head.

"For the layman," the journal says, "this controversy appears in a very simple form. Granted that the German physicians understood the nature of the malady better than the English doctor, could they guarantee to their patient a complete recovery, or give him a longer lease of life than Mackenzie did? That alone was the question which confronted the *wife* of the patient, denounced and insulted by German hirelings as the 'Englishwoman,' despite the fact of her being the daughter of a German prince."

It was for the *woman*, who loved her sick husband, to decide, for the woman, who wished to see his life prolonged, to choose between a plan of treatment that gave her grateful hope and another plan which, in a strictly scientific way, perhaps, but at the same time with brutally cruel frankness, thrust a decisive "either—or" upon her. What wonder then, that, like every true German woman—like any loving wife would have done, she chose the former alternative, *i.e.*, Mackenzie. She could not view things from the stand-point of the surgeon, who may congratulate himself on the successful accomplishment of a brilliant operation, while he has but a passing shrug of the shoulders for the unfortunate circumstance of the patient's early death. The supreme wish of the wife was to see her husband's life spared, to nurse him faithfully with unflagging courage to the bitter end, to be to him as he shortly before his death called her, his tireless "maid of all work." The wife had no concern for the glory of German science, for the great fame of distinguished savants. As long as an English "charlatan, humbug, imbecile, swindler," etc., as he has been dubbed by royal-imperial permission, extended to her the one hope of preserving for at least a few months longer the life of the father of her children, so long would she accept his less heroic treatment for the uncertain chance of a formidable surgical interference. So much for the layman's reasonings.

Though we, as physicians, are apt to pay little heed to the judgment of the lay world, so far as medical problems are concerned, it is never harmful to see ourselves as others see us. We will do well to occasionally try to put ourselves in others' shoes. We all have our lessons to learn. The German can doubtless teach us much in the way of abstract science; and it is quite possible that we can teach him a little something in the direction of the *suaviter in modo*. One thing is certain—it is never out of place to have a humane appreciation of the fact that, besides being objects of pathological inquiry, the sick are also subjects with feelings that have no relation to physical laws and the material world.

THE AMERICAN ACADEMY OF MEDICINE.

THE American Academy of Medicine holds its next annual meeting in this city about the middle of November. The energy and ability of the President, Dr. Frederic H. Gerrish, have been actively exerted in securing a good attendance and interesting papers. The American Academy occupies a peculiar and distinctive position among our national organizations. Its objects are educational and literary, including the "subjects of the education of the physician, both preliminary and technical; of the relations of the profession to the public, to its sister professions, and to the State; of the profession in this country to that of other countries; of the status of members of our profession in the service of the United States or of the several States; of medical literature, including history and biography, and cognate themes having reference to the elevation of the literary, scientific, and social standing of the profession."

The field of work offered by the Society is a praiseworthy one, and cannot be too diligently cultivated.

Membership in it involves no annual dues, and is accessible to all physicians of at least three years' experience in practice who, previously to graduation in medicine, had received the degree of bachelor or master of arts.

The Society is steadily growing, but membership in it is an honor which should be still more widely desired.

The Academy has held very few of its meetings in this city, and we trust that its present one will prove most successful.

We shall announce the programme of work later.

THE TREATMENT OF PHTHISIS BY BAKING.

DR. LOUIS HALTER, after showing that workers in lime-ovens (kalköfenarbeitern), who are subjected to high degrees of dry heat do not suffer from phthisis, deduces a method of phthisis therapy based upon these facts (*Berl. klin. Wochenschr.*, No. 38, 1888). The causes of immunity in the class referred to he believes to be:

1. The great dryness of the air in and about the ovens.
2. The rarefaction of the air in consequence of the heat. and its freedom from tubercle bacilli from the same cause.

The workmen are subjected once or twice daily, for ten to thirty minutes, to intense heating of the body—105 to 160° F.—with consequent increase in pulse and respiration rates, diaphoresis, and rapid tissue-changes. They drink immense quantities of water and considerable quantities of alcohol.

Dr. Halter says that the temperature of air in the lungs normally is about 37° to 38° C., which is that most favorable to the development of the tubercle bacillus. If, now, the inspired air be raised in temperature to 45° or 50° C., the air in the lungs will be heated beyond the point favorable to bacillary growth. He proposes to subject phthisical patients to such hot inhalations several times daily, and he pictures an apparatus devised for this purpose.

The idea of breathing sterilized air is well enough. No doubt it is upon this fact of a germ-free atmosphere that most health-resorts for consumptives depend for their reputation. A sterilized air, however, is not quite enough, otherwise sea-voyages would be as beneficial as mountain-resorts. The dryness of the air is an admittedly valuable factor in the climato-therapy of phthisis. The additional idea involved in Halter's apparatus for baking the bacillus in its alveolar nest by inhaling a fiery atmosphere, and, perhaps, in addition, of producing a temporary artificial fever, for the sake of increasing tissue-change, seems highly theoretical.

At the same time, and independently of Dr. Halter, an American physician, Dr. Weigert, residing in Berlin, has been making experiments in the same direction as that of Dr. Halter.

Dr. Weigert, finding that tubercle bacilli outside the body die at a temperature of 41° C., and are adversely affected by one of 38°, has had constructed an apparatus for the inhalation of heated air, and commenced to make trials on phthisical patients in the early stage recommended to him by other medical men, he himself not being in practice. At first a temperature of from 40° to 60° C. was employed, the air for inhalation being quite dry. This temperature was gradually raised as high as 80° C. The patients bore this hot, dry air exceedingly well, and continued to inhale it for three or four hours a day during a month, the only unpleasant effects produced being hyperæmia and dryness of the mucous membrane. The general effects are represented as having been remarkable, patients who had been falling away picking up strength and becoming quite robust, the physical examination showing at the same time that the dulness and râles had perceptibly decreased. The bacilli in the sputum, which had been very numerous, rapidly diminished in number, and finally disappeared altogether. These observations were confirmed by several other medical men.

Despite these alleged successes, one can hardly believe that a temporary heating of the air-passages daily can really affect the pathological processes in the lungs, or the development of the bacilli implanted deep in its structures.

PARIS DOCTORS AND DOCTORS SIGNS.

THE Paris correspondent of the *New York Medical Journal* says: "One of the rather curious facts in regard to medical customs in France is the difficulty a stranger has of finding a physician's house, notwithstanding the fact that Paris has as large a proportion of physicians as any other city—not excepting some American ones. The greater number display no sign, and when you know that in Paris one house is as like another as two peas, it is easy to imagine the trouble of finding the right house when on the search for a doctor. Not only is there no 'shingle' on the front door, but there is not one even on the door leading to the office—not even a card to show the stranger who lives in the *appartement*.

"Among the cheaper class of physicians will be found a small sign saying, '*Docteur en Médecine, de* 1 *à* 3 *heures*,' but no name is given; and as to the better class, not the slightest indication is given that they live in a house. It is a curious Parisian custom."

A slight tendency toward the Parisian idea in signs would be an excellent thing to infuse into the profession in this country, or at least some portions of it.

The size and prominence, the gilded or polychromatic aggressiveness of doctors' signs, depend measurably upon local custom. But, as a general rule, the bigger the sign the poorer the doctor, the more conspicuous the sign the more incompetent its owner.

Death loves a shining mark.

THE CLASSIFICATION OF FEES.

THE Russian authorities have undertaken a paternal direction of the amount of the fees which medical men shall receive. They have gone much further than establishing a one-price schedule such as many societies in this country have adopted. They have tried to "size up" officially the different classes of patients, and prescribe the amount of money that shall be extracted from each. Their classification is as follows: The first and highest-priced class are capitalists, owners of real estate, merchants of the first rank, manufacturers, civil officers of the first to the sixth class. The second category includes civil officers having an income of over one thousand rubles, merchants of second class, agents, drummers, teachers. The third class includes everyone else. The fees depend not only upon the financial rank of the patient but also upon his place of residence. Thus in the country, and smaller towns up to those of ten thousand inhabitants, the fee to persons of the first class is one ruble (about seventy-five cents); to those of the second class, seventy-five copecks (about fifty cents); in the third category, fifty copecks.

In cities of between ten thousand and one hundred thousand inhabitants the fees are one hundred and fifty copecks ($1.20), one ruble, and sixty copecks, respectively. In cities of more than one hundred thousand inhabitants the fees are two rubles ($1.50), one hundred and fifty copecks, and seventy-five copecks, respectively. For night-visits, *i.e.*, after 8 P.M., fifty per cent. is added.

The classification above given is not one legally enforced, if we understand the description correctly, but is that which is officially recognized, the normal one to serve as a basis for taxing. The principles employed in arranging the schedule are correct, or, at least, are in accordance with those which, as a matter of fact, gradually become adopted by the medical profession. The rich have to pay more in order that the poor may be treated for nothing, or for a nominal fee. The maximal price depends upon the condition of the patient, the expenses incurred in living, which are always greater in large cities.

Rigid regulations of fees, however, always fail in free countries, more often because the doctor drops below the normal in his charges than because he rises above it. In large cities there are especially great variations in prices, both in the maximum and minimum fees.

News of the Week.

THE ANNUAL REPORT OF THE SURGEON-GENERAL OF THE UNITED STATES ARMY has just been issued. From this we learn that our army medical service is expected to cost about $230,000 next year. In a chapter on the health of the army, Surgeon-General Moore says the mean strength of the army for the year, including officers and both white and colored enlisted men, is stated at 23,841, of which 21,601 were white and 2,240 were colored. The total admissions to sick report were 29,727; white, 26,600; colored, 3,127. Ratio of all admissions per 1,000 of mean strength, 1,231.42 white and 1,395.98 colored. Admissions for disease, 21,438 white; 2,450 colored; total 23,888. Admissions for injuries, 5,162 white; 677 colored; total, 5,839. Average number constantly non-effective during the year, 907.08 white; 103.20 colored; total, 1,010.28. Number of days lost on account of sickness, 368,754. The death-rate was somewhat lower than that for 1886, when it was 8.82, and considerably lower than the rate for the previous decade, which was 11.4. The death-rate continues to be higher than that of any of the foreign armies except the British and Italian. The principal causes of deaths were pneumonia and shot wounds. The Surgeon-General says that the large number of disabled officers of the medical department seriously embarrassed its efficiency, and recommends the retirement of those officers who have been incapacitated for active service by retiring boards, and their places filled by young and active men. He also recommends an increase in the force of twenty assistant surgeons.

"SLOYD," OR WHITTLING, AS A MEANS OF EDUCATION.—The old Yankee pursuit of whittling has got round to

Sweden, where it has been scientifically studied and applied to purposes of education and amusement under the name of "Sloyd." The *British Medical Journal*, commenting on this subject, says that the main differences between wood sloyd and ordinary carpentering, with which it is very apt to be confused, are these: 1. The objects made are usually smaller than those made in the trade. 2. As to tools used; the knife, for instance, is the most important of all in sloyd. 3. All parts of the work are done by the pupil. 4. The objects of sloyd are to develop the faculties, not to make carpenters. A careful choice is made of the models; the objects selected are such as may be used at home; both soft and hard woods are used. It is often a difficulty in medical practice to suggest amusement and occupation for patients who must keep in-doors for a prolonged period, and who yet preserve an active temperament. "Sloyd" is a form of work which calls forth every variety of movement, and exercises both sides of the body, for it is so arranged that the children can work with the left hand and arm as well as with the right in sawing, planing, etc. In the schools of Norway classes in sloyd are held both for boys and girls. An association has been formed for the introduction of sloyd into England, and for the purpose of training teachers in the art. New England ought to be able to furnish some professors of the art of whittling.

THE PHARMACY LAW IN THIS STATE REQUIRES all preparations of opium and morphine except paregoric to be labelled, such label being on scarlet paper with white letters; while a law passed June 21, 1887, provides that whenever a prescription contains opium or morphine in which each dose of opium exceeds one-fourth of a grain, or morphine one-twentieth of a grain, the prescription shall not be repeated except on the verbal or written order of a physician.

RECEPTION TO DR. W. O. PRIESTLEY OF LONDON.—Dr T. Gaillard Thomas gave a reception on the 22d inst., at his residence, to Dr. William Overend Priestley, of London. It was largely attended by representative medical men of the city.

STATE VITAL STATISTICS AND THE STATE BOARD OF HEALTH.—The *Sanitary Era* accuses our State Board of Health of inaccuracy in making up its vital statistics. The average death-rate for specified localities is, we are told, obtained by dividing the total sum of the local death-rates by the number of the localities. "To illustrate, the little town of Crown Point, with 4,287 inhabitants and a death-rate of 2.80, counts one against one with the city of New York and its 27.73 in a million and a half, and makes an average of 15.27 between them. On the other hand, Saratoga with 54.00 averages with New York up to 40.43; when in fact the combination rises only to 27.77."

THE HOAGLAND LABORATORY of Brooklyn is completed and open for work. Dr. George M. Stirnberg is Director, and Dr. George T. Kemp, of Johns Hopkins University, Associate Director.

DR. JOHN W. S. ARNOLD, formerly Professor of Physiology in the University Medical College of this city, died October 20th at Sewanee, Tenn. He was born in Charleston, S. C., May 16, 1846. He was educated at Columbia College, from which he graduated in 1868 with the degree of A.B., subsequently, in 1871, receiving the degree of A.M. In 1871 he also graduated from the Bellevue Hospital Medical College, and began the practice of his profession in this city. Dr. Arnold made a specialty of physiology and microscopy, and wrote extensively on medical subjects. He filled the chair of Normal and Pathological Histology and of Physiology and Histology in the Medical College of the University of the City of New York, and was at the same time Curator in Bellevue Hospital.

PASSED ASSISTANT SURGEON CUNNINGHAM W. DEANE died on board the coast survey steamer MacArthur at San Francisco October 22d. He was a native of Richmond, Va.

RECENT SURGICAL ACHIEVEMENTS: GASTRO-ENTEROSTOMY AND CHOLECYSTENTEROSTOMY.—Dr. F. Fritzsche, of Glarus, has just published a detailed account of two successful cases of Woelfler's gastro-enterostomy for stenosis of the pylorus. In one, that of a man, aged fifty-seven, the stricture was malignant, while in the other, a woman, aged thirty-seven, the case was one of simple cicatricial contraction. Both patients made an excellent recovery. The man, who had weighed only forty-four kilogrammes before the operation, was found to weigh fifty-four kilogrammes and to have a healthy appearance about three months later, in which state he still remains up to the present (about seven months after the operation). He has no symptoms whatever, except a sensation that the food ingested stays in his stomach only for a short while, so that he is compelled to eat frequently in order to appease his hunger. Similarly, the woman's weight rose from thirty-eight kilogrammes before the operation to forty-eight in two months after it. When seen seventy-seven days after the gastro-enterostomy she stated that she "was quite well, and could eat safely even such things as sauerkraut with lard." At a recent meeting of the Medicinische Gesellschaft, in Basel, Professor Socin read a paper on a successful case of Kappeler's cholecystenterostomy, performed by him in a highly emaciated, weak woman, aged fifty-one, with complete obliteration of the bile-duct, and consequent dilatation of the gall-bladder. Having opened the abdomen by a free incision along the outer edge of the rectus on the right side, he cut into the bladder to remove four hundred cubic centimètres of bile (not containing any concretions); he then made an incision three centimètres long in the jejunum, and stitched the intestinal wound to that in the gall-bladder. Three days later the bowels were opened for the first time, the stools being normal in appearance. Jaundice rapidly disappeared. In forty-one days the woman's weight rose from ninety to ninety-nine pounds. This is the second recorded case of cholecystenterostomy.—*Cor. British Medical Journal.*

A CHEAP BOY.—A Dutch missionary in Africa bought a negro boy two years old, who was deaf and dumb, for six pounds of salt. On account of his infirmity, but for the interposition of this missionary, the child would have been put to death. He is now a pupil in the institution for deaf mutes at Maestricht.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Annual Meeting, October 22, 1888.

L. Bolton Bangs, M.D., in the Chair.

REPORTS OF OFFICERS AND STANDING COMMITTEES.

Alexander S Hunter reported a balance in the treasury of $77.20. Dr. Bruce, Secretary of the Committee on Ethics, reported progress. Dr. John Warren read the Report of the Board of Censors, particularly regarding the prosecution of illegal practitioners.

THE MEDICAL DIRECTORY.

Article V., of Chapter VIII., of the By-laws was amended to read as follows: It shall be the duty of the *comitia minora* to provide for the annual publication of the Medical Directory of the City of New York.

It was thought that, as last year, the advertisements would pay for the issuing of the directory.

While the polls were open for the election of officers, Dr. Paul F. Mundé read a paper,

THE VALUE OF THE OPERATION OF SHORTENING THE ROUND LIGAMENTS OF THE UTERUS,

based on the results of twenty-three cases.

Having been the first to do the operation in this country (December 12, 1884), and the question of its technique and value being still under discussion, the author thought he was justified in presenting his further experience in a paper this evening.

Since the publication of his first two articles his views regarding the difficulty of finding the round ligament had changed. He now believed that his failure to find the ligament in certain early cases was due to not recognizing certain anatomical landmarks. In his paper he directed attention to three questions: 1. Could the round ligaments always be easily found, drawn out, and thereby the uterus be elevated and everted? 2. In which form of displacement of the uterus was the operation indicated, and likely to be followed by lasting relief? 3. Was elevation and suspension of the uterus by shortening the round ligaments alone followed by permanent results, or did it require a further operation on the vaginal floor? On these points great diversity of opinion existed. Some, principally the Germans, objected to shortening the round ligaments on theoretical grounds, others because they had had difficulty in finding the ligaments, or because they failed to supplement the operation with a plastic operation on the pelvic floor.

Dr. Mundé attributed his failure to find the ligaments in his first cases to following too closely the directions of the inventor of the operation; he failed to find exactly the external ring and to pick up the terminal filaments of the ligaments. Experience had taught him to feel for the spine of the pubis, to mark it, and being careful not to draw the skin aside, make a quick oblique incision, from one and a half to two inches in length, directly down to the spine so as to almost nick the periosteum. Through the incision thus made there popped up a bunch of fat, which during the further steps of the operation should not be lost sight of, since in it were contained the terminal filaments of the ligament. As soon as the outlines of the ring were found, the whole pouting mass should be lifted with the forceps, gentle traction made, when it would be found to extend by connection with the terminal filaments of the ligament to the pillars of the ring where the cord was attached. In three quarters of his cases there was healing of the wound after the operation by first intention; sometimes there was some suppuration, particularly in fat patients. In fat subjects the incision would need to be a little longer, but the ligament could be found with equal ease, although formerly he thought differently.

Two of the chief objections to the operation, which could not be discovered beforehand, were, first, that the ligament might be too small to support the uterus, as when it was no larger than a knitting-needle; second, when there were adhesions in the canal, causing it to break before it could be drawn out.

Regarding the indications of the operation, where the uterus was displaced backward, was non-adherent, there was relaxation of the vagina and pelvic floor, shortening the round ligaments would do more than any other measure toward retaining the uterus in place; but Dr. Mundé emphasized the fact that adhesions of the uterus absolutely forbade the operation. If there was complete prolapsus of the uterus and vagina it was expecting too much of the ligaments to support the uterus with the vagina dragging upon it; a plastic operation on the pelvic floor was necessary.

Replying to the third question, Dr. Mundé said that nineteen of his twenty-three cases were successful; in two the ligaments were not found; in two both were torn off. Of the nineteen cases, which had been kept under observation from three months to three years and a half, in all the uterus was retained in the position it occupied when the operation was concluded. But in only seven of the twenty-three cases was Alexander's operation alone performed. In view of the results recited, he expressed himself decidedly in favor of the operation in properly selected cases, for it usually accomplished what was desired, with very slight risk and little pain or inconvenience to the patient.

Dr. H. T. Hanks thought the Alexander operation had its legitimate sphere, but he believed it had been done in this country where not called for, and by persons who should have devoted much more time to searching for the round ligaments on the cadaver before attempting the operation on a living subject. He had seen Alexander search fifteen minutes for the two ligaments.

Dr. H. J. Boldt would still further limit the operation in the class of cases pointed out by Dr. Mundé to those in which at the point of flexion in the uterus there was such atrophy and loss of vitality that it could by no means be restored. In many other cases, where the operation was now done, he would employ Brunt's system of gymnastics to the uterus and pelvic organs.

Dr. Andrew F. Currier thought the chief difficulty of the operation related to finding the ligaments, which could be facilitated by making a slight incision up the transversalis fascia after reaching the ring, which would permit the fat to pout out much more readily. He thought the operation on the ligaments and the supplementary plastic operations should be performed at different times.

The paper was further discussed by Drs. Abbott and Lesser.

The tellers announced the result of the election as follows: For president, Dr. Alexander S. Hunter; vice-president, Dr. L. Bolton Bangs; for secretary, Dr. Charles H. Avery; for assistant secretary, Dr. William E. Bullard; for treasurer, Dr. John S. Warren; for censors, Drs. J. Leonard Corning, Maurice N. Miller, Daniel Lewis, Andrew F. Currier, and Laurence Johnson.

Dr. Washburn offered the following resolutions concerning the water supply of the city passed at the last meeting of the Society, which were laid on the table.

Whereas, A resolution was passed at the last stated meeting of this Society endorsing a private scheme in the following words, viz.: (See Medical Record, September 29, 1888, page 402.)

Whereas, In the judgment of this Society it was an error which is calculated to break the force and destroy the influence for good, of this, as a scientific body; therefore be it—

Resolved, That the foregoing resolution be, and the same is, hereby rescinded. And be it further

Resolved, That while this Society does not endorse any particular scheme, it desires to emphasize the fact that the present deficient water-supply is a menace to public health and should be supplemented, at the *earliest possible* date, by accessions from *any* source that will the most *perfectly* and *promptly* supply the city's pressing necessity; and urges upon those having authority, to institute such means as will procure for this city *the most ample supply of pure* water at the earliest possible moment.

On motion of Dr. A. S. Hunter the annual dues for the ensuing year were declared to be three dollars.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, October 18, 1888.

ABRAHAM JACOBI, M.D., PRESIDENT, IN THE CHAIR.

DR. M. ALLEN STARR read a paper (see p. 419) on

APRAXIA AND APHASIA: THEIR VARIETIES, AND THE METHOD OF DETECTING THEM.

DR. W. R. BIRDSALL thought the subject treated of by Dr. Starr formed a sort of oasis in the desert of neurological investigation, and that our present knowledge of it had been very clearly stated. Reference has been made to preservation or loss of the musical faculty in aphasia, and he was reminded of the first case in which he had independently made a diagnosis of aphasia. The subject was rather illiterate, and was accustomed to play the violin at balls. He was almost totally aphasic and agraphic, being able only to say yes and no, and to write and speak his name. There was neither word-deafness nor word-blindness. There was no interference with the musical faculty, for he could read notes and play the violin as well as before his attack. The case showed that the nerve-tracts concerned in musical ideas were independent of those of speech.

He thought Dr. Starr's diagram must have involved a great amount of labor, and such an analysis of pathological cases was of much greater value in cerebral localization than laboratory investigations.

DR. E. D. FISHER had seen one of Dr. Starr's cases, and had recognized the difficulty of determining the presence or absence of hemianopsia, and during the examination it had occurred to him that it would be difficult to determine, in many instances of so-called sensory aphasia, whether the lesion was localized in some particular part of the gray substance of the brain, for to him it was difficult to say where the general intelligence lay in the cerebral substance. It was, he thought, impossible to say that it lay in the frontal lobe, or whether it was not in the whole cortex. Therefore, in so-called sensory aphasia there might be something besides a localized lesion which apparently was pointed to. There might be general loss of intelligence represented by some cortex degeneration, not a localized degeneration. There were cases of so-called localized motor aphasia in which the patients seemed to have lost understanding in a general way, and seemed to lack knowledge of affairs; yet at death a lesion was found involving Broca's convolution and no lesion involving the sensory area. It seemed likely that, in many cases, instead of a localized lesion there was some interference with the whole sensorium.

Again, admitting that there were special sensory and motor centres, it would be rather difficult to say that such centres were affected; only the association fibres might be involved, while the cells in the cortex, the psychical centres, were not involved. It was a very interesting study to distinguish between lesions of the white substance and of the gray matter. In motor lesions the diagnosis was less difficult.

THE PRESIDENT agreed with Dr. Fisher regarding the existence of difficulties in diagnosis which he had pointed out. They had been recognized by a number of prominent neurologists. For instance, symptoms had been found to exist which, according to some, should point to a definite localized lesion, yet the autopsy revealed an extensive lesion. On the other hand, in some cases in which at the autopsy only a local lesion was found, yet there had been a large number of different results. Quite a localized embolus might give rise to fever, to active congestion, convulsions might set in, and a number of cerebral symptoms which did not belong to a local lesion. But Dr. Starr seemed to have shown that a number of cases were on record, verified by autopsies, in which definite symptoms had followed definite local lesions.

DR. PUTNAM-JACOBI thought Dr. Starr's diagram was imperfect, that it explained only the loss of verbal signs, of simple words, of nouns, and did not explain the loss of language where a number of ideas were involved. She asked the author in how far lesions had been found in aphasia in parts of the brain other than those associated with the visual, auditory, or tactile centres, and not including cases of diffuse lesions of the brain in which there would, of course, be more or less interference with language as with all the mental powers.

DR. A. H. SMITH remarked that years ago he was studying a case of aphasia for some time, and it occurred to him that the condition might be expressed as one of "psychical inco-ordination," an inability to associate properly the mental processes and the motor impulses necessary to give expression to them.

DR. STARR, in closing the discussion, said he thought the diagram of cases would aid in replying to Dr. Putnam-Jacobi's question, viz.: Whether lesions in other parts of the brain than those referred to by him would produce the symptoms and affect the mind, or cause disturbance in what had been called the intellectual centre? The various diagrams presented by different authors had upon them an intellectual centre, such a one as Dr. Putnam-Jacobi had referred to, and with which all the various memory-centres were connected by converging lines. The question suggested itself to him, when looking over those diagrams, was there such an intellectual centre? He did not believe there was. He believed there was no such thing as an intellectual centre in which we had an idea of such a thing as a bell. If so, then we ought to find lesions of the brain causing loss of such idea while recognition of the object remained—two things which were incompatible. The concept "bell," he thought, was explained by the existence of the three independent centres figured in the diagram, and the concept was complete only when the three centres were intact. The supposition of an independent intellectual centre for the concept bell would be equivalent to supposing a wheel was something aside from the hub, spokes, and tire composing it. There was no necessity for a further intellectual centre in the brain for an idea of the word "bell." When we found that no lesion of the brain would destroy the idea of a bell entirely unless that lesion affected all the centres in the diagram, we came to the conclusion that there was no necessity for such a centre. The term suggested by Dr. Smith, psychical inco-ordination, was a very applicable one, as that was the condition present when the sensory centres were destroyed. He thought the discussion had enforced the value of pathological observations as distinguished from physiological. Animals might certainly have certain symptoms after the destruction of certain brain areas, but the symptoms which were detected were very likely to be those for which the physiologist was searching, and if he failed to search for a symptom which might be present, that symptom the animal could not explain or make known. Therefore, he thought that the results of experiments on the brain of animals were far less satisfactory than the observations of pathologists of local lesions in man.

The Academy indorsed a resolution requesting the council to exercise its power in purchasing a new site and erecting a building. After a start should have been made it would be easier to raise the necessary additional funds.

Reviews and Notices of Books.

Intestinal Diseases of Infancy and Childhood. By A. Jacobi, M.D. No. 5 of Physician's Leisure Library. Detroit: George S. Davis. 1887.

This timely publication, while containing nothing new, will nevertheless be read with pleasure and profit, especially by the younger members of the profession. The various topics belonging to the subject of intestinal diseases of the young are treated in a rather fragmentary but yet suggestive manner. Practical hints in the management of these disorders abound in this unpretentious manual, and altogether it can be safely commended to the attention of the profession.

The Practice of Medicine and Surgery Applied to the Diseases and Accidents Incident to Women. By W. H. Byford, A.M., M.D., Professor of Gynecology in Rush Medical College, etc., and Henry T. Byford, M.D. Fourth Edition. Philadelphia: P. Blakiston, Son & Co. 1888.

Byford's treatise on the diseases peculiar to women is already well known to the profession in this country. The author is often too positive in his assertions, especially where methods peculiar to himself are concerned. The student and beginner may be misled by teachings that do not always represent what is accepted by the great body of gynecologists. For the more advanced student, however, whose own experience will enable him to either accept or reject doctrines and methods, this work will prove entertaining, suggestive, and instructive. Some of the drawings are old acquaintances, though scarcely old friends. The majority, it seems, were specially prepared for this volume, and are in the main commendable. It is quite evident, however, that some of the exploring fingers found depicted within the genital organs must have at least one more phalanx than those commonly owned by Dr. Byford's Eastern confrères; indeed, one particular finger, at page 94, probably has two of these supernumerary phalanges. We envy the possessor of such gynecologically perfect digits, which doubtless makes the *tactus eruditissimus* his inalienable birthright.

Diseases of Women: A Handbook for Physicians and Students. By Dr. F. Winckel, Professor of Gynecology and Director of the Royal University Clinic for Women in Munich. Authorized Translation by J. H. Williamson, M.D., Resident Physician Allegheny General Hospital. Under the supervision and with an introduction by Theophilus Parvin, M.D., Professor of Obstetrics and Diseases of Women and Children in Jefferson Medical College, Philadelphia. Philadelphia: P. Blakiston, Son & Co. 1887.

Winckel's handbook is a work that will be profitably consulted by all classes of gynecological practitioners. It contains better and more elaborate pathological descriptions than any work of its kind in the English language that we are acquainted with. The German school of scientific gynecology is worthily represented by this treatise, and the English reader will feel grateful for having the often difficult original rendered into smooth and readable English. As a text-book for students, as well as a work of reference for the practitioner, we can conscientiously recommend Winckel's "Diseases of Women."

Medical Lectures and Essays. By George Johnson, M.D., F.R.C., F.R.S Pp. 900. London: J. & A. Churchill. 1887.

In this large volume the patient and painstaking research of thirty years is set before the reader. The medical lectures and essays published at various times during this period have been gathered together. The author writes upon the physiology of the circulation, upon cholera, and some nervous diseases as well as many other topics.

Essentials of Chemistry and Toxicology. By R. A. Witthaus, M.D., Professor of Chemistry of the University of the City of New York, etc. New York: William Wood & Company. 1888.

This pocket manual for the use of medical students has reached its second edition. In a series of over a thousand questions and answers it brings out the important facts concerning medical chemistry. Toxicology is considered not only in its purely chemical aspects, but the main symptoms are given for individual cases. It is difficult to see how it could be improved upon.

What to Do First in Emergencies. By Charles W. Dulles, M.D., Surgeon to University Hospital, etc., Philadelphia. 12mo, pp. 123. Philadelphia: P. Blakiston, Son & Co. 1888.

This is written in popular language, and is intended to furnish information for emergencies until a physician may arrive. It is therefore a "First Aid" hand-book, and, we think, is in many respects superior to the official publication of the society alluded to. For its toxicological portion it cannot, of course, be compared with Murrell's recently published book, as it covers a different field entirely. The use of type of different sizes and a complete index render reference to any topic perfectly easy even for a novice. The writer is to be congratulated on his success in putting so much scientific information in such simple language.

Diseases of the Heart and Circulation in Infancy and Adolescence. By John M. Keating, M.D., and William A. Edwards, M.D. 8vo, pp. 215. Philadelphia: P. Blakiston, Son & Co. 1888.

The ten chapters which compose this treatise were published in instalments in the *Archives of Pediatrics* last year, though they have been much changed and added to since their first appearance. The authors have done valuable service in condensing into one book a vast amount of material which was scattered throughout medical journals, society reports, lectures, etc. The opening remarks on Methods of Study should be carefully read by everyone commencing medical practice, and, in fact, no library of reference can be considered complete without the book. Two excellent photographs illustrate the chapter on mitral lesions. There is always a tendency to exalt physical signs over symptoms in writing on heart and lung diseases. This is a modern leaning toward one side which is to be greatly deplored, because it gives only half the truth. Drs. Keating and Edwards have not omitted the physiological factor in diagnosis by giving too much prominence to the physical factor. We mark this complete volume as a praiseworthy contribution to the literature of pediatrics.

A Reference Handbook of the Medical Sciences: Embracing the Entire Range of Scientific and Practical Medicine and Allied Sciences. By Various Writers. Illustrated by Chromo-lithographs and Fine Wood Engravings. Edited by Albert H. Buck, M.D., New York City. Vol. VI. New York: William Wood & Company. 1888.

The sixth volume of this work contains articles from "Prairie Itch" to "Teplitz-Schönau," and fully sustains the reputation which it has already earned for scientific thoroughness and practical utility. Among the larger subjects treated of are Professional Neuroses, Prostate, Ptomaïnes, Puerperal Condition, Quarantine, Poisonous Reptiles, Resection, Sanitary Inspection, Scarlet Fever, Schizomycetes, Secretion, Sewage, Small-Pox, Spectacles, Spinal Cord Diseases, Stomach Diseases, Suicide, Syphilis, and Teeth. Those mentioned are only a few of the longer articles, but there are literally hundreds of other subjects of equal importance in their way, but which require less exhaustive treatment. Among these may be mentioned the various articles on organic and inorganic medicinal agents, health-resorts, regional anatomy, pathology, new-growths, skin diseases, etc. We can only repeat what we have said so often, in noticing the earlier volumes of this "Handbook," that it is a work which not only the active practitioner, but the scientific student as well, can ill afford to be without, for it contains a mass of information which no man, be he ever so learned, will not find of use at some time. The title is well chosen, for the work embraces indeed the entire range of scientific and practical medicine and allied science.

The Medical Register of New York, New Jersey, and Connecticut. For the year commencing June 1, 1888. Published under the supervision of the New York Medico-Historical Society. William T. White, M.D., Editor. Vol. xxvi. New York: G. P. Putnam's Sons. 1888.

The physicians of New York are now well supplied with directories. The "Register" is about the same as in former years, with the exception of a new table of stillbirths and deaths in New York for the past eighty-four years, and one of births and marriages since 1847, together with the population and ratio of mortality for the same period. The list of physicians in the State, outside of New York and Brooklyn, is arranged alphabetically as well as by counties. The book contains the names of 6,976 physicians.

The Medical Directory of the City of New York. Published under the auspices of the Medical Society of the County of New York. New York: Stettiner, Lambert & Co. 1888.

The "Directory" is for the convenience chiefly of members of the County Society, but contains the names and residences of all the registered physicians in the city. In a limited field it answers the purposes of a medical directory as well as does the older publication. We notice, however, several errors and omissions in it, which might perhaps have been avoided by more careful editing.

Food Adulteration and its Detection, with Photo-micrographic Plates, and a Biographical Appendix. By Jesse P. Battershall, Ph.D., F.C.S., Chemist United States Laboratory, New York City. Pp. 328. New York: E. & F. N. Spon. 1887.

Dr. Battershall's work goes into a new field, and presents systematically the results of the labors of chemists in the line of food adulteration up to the present time. It contains a bibliography and also an appendix, with a full account of the laws relating to food adulteration in this country.

The subjects presented include spices, oil, pickles, vinegar, water, liquors, wine, beer, honey, sugar, bakers' chemicals, flour, butter, milk, cocoa, coffee, tea, cheese, confectionery, miscellaneous.

The book is a much needed one, and ought to be of great service to the public. It is extremely well printed and the plates are all good.

Traité d'Électricité médicale. Recherches physiologiques et cliniques par les Docteurs E. Onimus et Ch. Legros Deuxième édition, revue et considérablement augmentée par E. Onimus. Avec 275 Figures dans le Texte. Pp. 1088. Paris: Félix Alcan, Éditeur. 1888.

There is no text-book on medical electricity which embraces the results of so much individual physiological research as the one before us, and few which present the results of a wider practical experience. Everyone interested in medical electricity, therefore, will find something of value in Professor Onimus' work. It is not, however, a systematic and complete text-book, and many of the author's physiological views are not fully accepted by the generality of scientific authorities of to-day. It is a book to be read critically.

Synopsis of the Physiological Action of Medicines, Prepared for the Use of Students, etc. By Louis Starr, M.D., James B. Walker, M.D., assisted by W. M. Powell, M.D. Third edition, enlarged. Philadelphia: P. Blakiston, Son & Co.

When this little work is enlarged again, we trust it will be made to include a larger number of drugs, and thus more thoroughly represent the Pharmacopœia.

The Language of Medicine: A Manual giving the Origin, Etymology, Pronunciation, and Meaning of the Technical Terms found in Medical Literature. By F. R. Campbell, A.M., M.D., Professor of Materia Medica and Therapeutics, Medical Department of Niagara University. Pp. 318. New York: D. Appleton & Co. 1888.

Dr. Campbell's work is that of a careful scholar, as such a work ought to be, and it supplies to the profession a most useful book. In particular, it should be in the hands of medical students and physicians whose knowledge of Latin is deficient.

Under Part II. the author gives a short Latin grammar, sufficient to teach anyone enough Latin for prescription writing and for understanding medical terms.

Part III. contains a short Greek grammar, adapted to the same purpose. There is a chapter on nomenclature, and a chapter on words commonly mispronounced. This latter ought to be read by everyone, with an eye to self-correction. The book is a thoroughly good one, and we commend it heartily to our readers.

Bibliothèque diabolique (Collection Bourneville). Procès criminel de la dernière Sorcière brûlée à Genève, le 6 Avril 1652. Publié d'après des documents inédits et originaux, conservés aux Archives de Genève. (No. 3,465.) Par le Dr. Ladame. Pp. 57. Paris: Aux Bureaux du Progrès Médical, 1888.

The title of this work tells its nature. It appeals to those interested in curious psychological and historical studies.

Chemical Analysis of Healthy and Diseased Urine. Qualitation and Quantitation. By T. C. Van Nüys, Professor of Chemistry, Indiana University. With thirty-nine wood engravings. Pp. 187. Philadelphia: P. Blakiston & Sons. 1888.

This little work is a most creditable one to its author and to American chemistry. It contains a much fuller account of the methods and results of the more complicated analyses of urine than is usually found. We have had so many small urinary hand-books for students, lacking in originality and completeness, that the present work is somewhat of an oasis in the arid desert of the average manual. Not that Professor Van Nüys has gone over the whole ground, but the part covered is covered thoroughly.

Leçons sur les Maladies du Système nerveux, faites à la Salpêtrière par G. M. Charcot. Tome troisième, deuxième fascicule. Paris, 1887.

Charcot's method of work is to present the results of his special investigations in the form of clinical lectures. These are at certain intervals collected and published. The present volume deals with functional neuroses especially. The lectures upon hysteria and its allied phenomena we do not regard as of much value to the American reader. The chapters on aphasia, myopathy, concussion of the spine, and chorea are, however, extremely valuable, and the volume on the whole is worthy of its author.

Manual for Hospital Nurses. By Edward J. Domville, M.D. With recipes for sick-room cookery. Pp. 100. Philadelphia: P. Blakiston, Son & Co.

This is a compact and useful little work, excellently arranged and printed.

TREATISE ON HUMAN PHYSIOLOGY FOR THE USE OF STUDENTS AND PRACTITIONERS OF MEDICINE. By HENRY C. CHAPMAN, M.D. Pp. 945. Philadelphia: Lea Brothers & Co.

WE receive one or two new physiological text-books every year, and there are already more in the field than can very well be utilized. Still, physiology is a progressive science, new facts are added each year, and new methods of presenting the subject are brought out. So we welcome the new-comers, hoping that each one will prove the ideal work.

Professor Chapman's work is a large one. It is very full of details in parts, and is particularly rich in descriptions of instruments and methods of physiological work. This, while making the book very useful for reference, lessens its value as a student's work. It is not, to be candid, a good student's text-book. It lacks the proper balance, giving as it does an excessive amount of detail in parts, and being deficient in other parts, as in that devoted to the nervous system. It shows, however, that the author is an industrious and accomplished physiologist, and many chapters will possess a permanent value as representing the results of his observations and experiments.

JAHRESBERICHTE UEBER DIE FORTSCHRITTE DER ANATOMIE UND PHYSIOLOGIE. Herausgegeben von DR. L. HERMANN und DR. G. SCHWALBE. XV. Bd., Literatur. 1886. II. Abtheilung, Physiologie. Leipzig: Verlag von F. C. Vogel, 1888.

ZUR PATHOLOGIE UND HYDROTHERAPIE DES FIEBERS. Von PROF. DR. WILHELM WINTERNITZ, unter Mitwirkung der Herren Dr. L. Sweinburg, Dr. A. Winternitz, Dr. J. Pollak, und Drnd. O. Pospischil. Pp. 78. Leipzig und Wien: Franz-Deuticke. 1888.

WE shall refer to this interesting monograph later.

ELEMENTS OF PHYSIOLOGICAL PSYCHOLOGY: A TREATISE OF THE ACTIVITIES AND NATURE OF THE MIND. From the Physical and Experimental Point of View. By GEORGE T. LADD, Professor of Philosophy at Yale. 8vo. Pp. 696. New York: Charles Scribner's Sons. 1887.

PROFESSOR LADD has undertaken to embody in a systematic treatise the results of the numerous investigations in physiological psychology which have been made in recent years. His task was a most difficult one, especially for a person who is not a trained physiologist or anatomist. It took him into a new field, since only Wundt's work had been written at the time the present one was finished. The works of Sergi and Herzen, which appeared in the same year, are inferior in method and completeness. The first part of the work is taken up with a description of the anatomy and physiology of the nervous system. The account given is remarkably free from errors, and though necessarily not complete or exhaustive, it yet gives the student an excellent idea of the present state of knowledge of this subject. The second part deals with the co-relations of the nervous mechanism and the mind; the third part with the nature of mind. Professor Ladd, though dealing with a branch of knowledge the students of which are mainly materialists or agnostics, is himself nothing of the kind. The mind he thinks has unity, reality, and spirituality. Mental phenomena are not, he thinks, atomic motions in the brain-cells, but are simply correlated to these. Professor Ladd is a dualist, we take it, and he defends his position by careful reasoning; yet we doubt if he convinces many. It is as difficult a task to prove that the mind is "immaterial" as to prove that it is "material." The common-sense of those who have familiarized themselves with nerve-physiology tends to convince them that mind is a form of force struck off by, or correlated to, the motion in the brain-cells, rather than an independent reality. Yet, when one tries to show how the Extended can produce the Unextended, he is very much at a loss. So we fancy that arguments over the nature of mind will continue indefinitely to be very indefinite in results. Professor Ladd's work, however, is, as a whole, to be greatly commended. It fills a want in literature, and its perusal can but be of great educational value to the physician.

PTOMAÏNES AND LEUCOMAÏNES; or, The Putrefactive and Physiological Alkaloids. By VICTOR C. VAUGHAN PH.D., M.D., Professor of Hygiene and Physiological Chemistry in the University of Michigan, and Director of the Hygiene Laboratory; and FREDERICK S. NOVY, M.S., Instructor in Hygiene and Physiological Chemistry in the University of Michigan. Philadelphia: Lea Brothers & Co. 1888.

IT is seldom that one finds, in these days, a book that is so full of information on a new subject as is this. Much has been written, it is true, concerning the animal alkaloids, of late years, but the articles are scattered about in various scientific periodicals, and are practically inaccessible to the busy man. The authors have therefore done a good work in collecting these materials and grouping them together in logical order where they can be of service to the ordinary reader. There are chapters treating of the foods containing poisonous ptomaines, of the relation of ptomaïnes to disease, and of the various methods employed in the extraction of ptomaines. The chemical, physiological, and pathological relations of the ptomaines and leucomaines are then considered at some length. This is, we believe, the only book in existence that deals methodically with this most important subject, and we can recommend it without hesitation to all who wish to inform themselves concerning this interesting study, which has such close relations with the etiology of many of the most common diseases.

THERAPEUTICS FOUNDED UPON ORGANOPATHY AND ANTIPRAXY. By WILLIAM SHARP, M.D., F.R.S., Licentiate of the Society of Apothecaries; Member of the Royal College of Surgeons; Fellow of the Royal Medical and Chirurgical Society; formerly Senior Surgeon of the Bradford Infirmary; now Vice-President of the Rugby Hospital. London: George Bell & Sons. 1886.

THE author of these essays seeks to establish the science of therapeutics upon laws rather than theories. Two of these laws, which he claims to have discovered and which he maintains are founded upon facts, are organopathy and antipraxy. By organopathy is meant the local action of all drugs. This has been treated of in former essays and is not considered at length in the present volume, which is devoted to the effort of proving the law of antipraxy. This term is employed to denote the contrary action of large and small doses of the same drug. The author is certainly convinced in his own mind of the truth of these two laws, and his book is written with the very laudable purpose of endeavoring to bring others to his own way of thinking.

THEINE IN THE TREATMENT OF NEURALGIA: Being a Physiological Contribution to the Therapeutics of Pain. By THOMAS J. MAYS, M.D., Professor of Diseases of the Chest in the Philadelphia Polyclinic; Member of the Philadelphia College of Physicians, of the Philadelphia County Medical Society, etc. Philadelphia: P. Blakiston, Son & Co. 1888.

THIS is a report of a series of experiments made by the author to determine the therapeutic action of theine. He shows that while the actions of theine and caffeine agree in many respects, yet in many important particulars they are very unlike. Theine affects more particularly sensation, causing, when injected in doses of from one-fifth to one grain, a decided anæsthesia in the parts below the seat of injection. The author relates a number of cases which seem to demonstrate that the drug exercises a decidedly beneficial effect in the relief of various forms of neuralgia and other painful affections. The little book will repay perusal.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

OPENING OF THE MEDICAL SCHOOLS FOR THE WINTER SESSION—THE INTRODUCTORY LECTURES—FRESH ATROCITIES AT THE EAST-END—A MURDERER WITH ANATOMICAL KNOWLEDGE—TWO NEW MEDICAL JOURNALS—OPENING OF THE MEDICAL SOCIETIES—A NEW OPERATION FOR VESICO-UTERINE FISTULA—PILOCARPINE IN OBSTETRIC PRACTICE—SIR MORELL MACKENZIE AND THE GERMAN DOCTORS—A NEW HOSPITAL FOR MANCHESTER—THE ARMY MEDICAL SCHOOL AT NETLEY.

LONDON, October 5, 1888.

DURING the past few days the medical schools have recommenced work, the winter session being, as usual, heralded by a chorus of "introductory lectures." Although at some schools the custom of having an introductory lecture is one " more honored in the breach than in the observance," it has so far survived the assaults made upon it that this year an introductory lecture has been delivered at seven out of the eleven schools. The subjects chosen by the lecturers have been various. At King's College the address was given by Mr. Erichsen, President of University College, and was largely devoted to the question of the desirability of establishing a new university in London—" for London and London alone." He maintained that the position of King's College and of University College justified them in asking for university rank, with power to grant degrees. He then addressed the students on the subject of their profession, and the qualifications for success in it. It was, he said, of great moment to learn to forget in medicine. Looking back on his own life, he found that, independently of minor advances, surgery had, during the last forty years, advanced in three distinct lines, which compelled every man engaged in surgical practice or teaching to become a student again, to throw aside a good deal of the knowledge he had previously acquired, and buckle to in order to acquire insight into the new order of things. The first of these was in connection with the pathology of tumors. Forty years ago the microscope was scarcely used in pathological anatomy, and the microscopical examination of tumors was utterly unknown. The next event was the introduction of anæsthetics into operative surgery. Perhaps the greatest revolution in modern surgery was that brought about by the introduction of that method of treatment, which was due to the untiring energy and the translucent genius of one of the professors of that college, a man who, he was proud to say, was a pupil and house-surgeon of his own—Joseph Lister.

At University College the address was given by Professor Ramsay, and was largely devoted to a consideration of the manner of thought of the middle ages in regard to science and medicine, as evidenced by the writings of the period. The lecturer then traced the connection between medicine and his own subject (chemistry), and referred to the value of the latter as a preliminary training for medical men. He then compared English with German students, to the advantage of the latter, who, he said, read to acquire knowledge, while our students read to pass their examinations. He attributed this partly to the fact that German teachers examined their own students.

At St. Thomas' Hospital Dr. Cullingworth discoursed on the preventability of puerperal fever. He said the mortality of childbirth was much higher than it was supposed to be, no fewer than 3,877 deaths having been returned as due to this cause in England and Wales in 1886, and the most reliable statistics went to show that the greater part of these deaths were due to puerperal fever. He believed that almost the whole of this mortality might in future be avoided, and puerperal fever be practically stamped out. He urged a more general use of antiseptics, which had already achieved wonderful results in obstetrics.

At the Westminster Hospital Mr. Stonham gave an elaborate address on the subject of medical education. He urged the desirability of rendering the preliminary examination in general education more severe, of lengthening the curriculum a year (from four to five), and he also pointed out the importance of senior students making themselves acquainted with those classes of disease which are not always met with in general hospitals, viz., infectious diseases, and the various specialties.

At St. George's Hospital Dr. Ewart discussed the medical man of the future, his training and his prospects. In what manner, he said, was the medical mind to deal with the enormous increase of knowable facts? and, on the other hand, how were medical practitioners to survive if their numbers maintained their present rate of increase?

At the Middlesex Hospital Mr. W. Foster urged the importance of giving chemistry a prominent place in medical studies; and at St. Mary's Hospital Dr. Waller's lecture was very largely devoted to describing the work which had been carried on in the physiological laboratory with regard to the electrical action of the human heart.

On Sunday last a further thrill of horror went through London, at the news that early on that morning two more women had been murdered at the East-end. One of them was much mutilated, being not only disembowelled in a similar manner to one of the previous victims, but also cut about the face in such a manner as to render recognition difficult, though the body has since been identified. A post-mortem examination disclosed that, in this case also, the uterus and portions of the adjoining parts had been removed and taken away by the murderer. It is said that the left kidney was also abstracted from the body. It is supposed that both these two last murders are the work of one hand, and that the murderer is identical with the perpetrator of the former crimes accompanied by similar mutilations. No clue, however, has as yet been discovered. In giving evidence at the inquest yesterday, Dr. Gordon Brown, Surgeon to the City of London Police, expressed the opinion that the murderer must have been a person possessing a good deal of knowledge of the position of the abdominal organs and the way of removing them.

It might have been thought that medical journalism in this country had reached its limits. Yet another aspirant for favor has, however, just appeared, styled *The Illustrated Medical News*. If the promise given by the first few numbers can be maintained in subsequent issues, there would appear to be room for the new venture. Whether it can be made a success commercially appears, though, very doubtful. Not only has each number been profusely illustrated with engravings, lithographs, etc., but a colored plate is issued weekly, and the price of the journal is only sixpence. Another medical periodical is also announced as to appear shortly, under the title of *The Journal of Dermatology*.

LONDON, October 12, 1888.

The commencement of the winter season is, as usual, signalized by the renewal of activity on the part of the medical societies. The Clinical Society meets for the first time this evening, and in the course of next week both the Pathological and Ophthalmological Societies will inaugurate their winter sessions. The first to take the field, however, has been the Obstetrical Society, which held its first meeting last week. Dr. Champneys then read a paper, in which he described a new operation for the cure of vesico-uterine fistula, which he had successfully performed in one case. The cervix was drawn down and the anterior vaginal wall dissected away from the cervix to beyond the limits of the fistula. A hole was thus left in the bladder and another in the cervix. These were closed with silver sutures and the vaginal wall repaired. Fifteen silver sutures were used. Dr. Percy

Boulton objected to the new operation, that the pelvic cellular tissue was opened up and freely bathed with urine, that the amount of necessary repair was more than trebled, since three large openings had to be closed, and that all the sutures put into the bladder and uterus were shut up and left behind, seven in the bladder and four in the uterus. Dr. Herman thought the operation was a great improvement, and suggested that the objection raised by Dr. Boulton, as to leaving the sutures, could be met by using catgut, which would certainly be absorbed. Mr. Doran referred to Bozeman's recent bold innovations in the treatment of urinary fistulæ. Dr. Champneys, in reply, said that he would in future use silk or perhaps chromic gut. He had used silver because he was anxious not to fail in a new operation on account of the sutures. With antiseptic irrigation there was no reason to dread opening up the cellular tissue, or the passage of a few drops of urine.

Dr. John Phillips then read a paper on the value of pilocarpine in pregnancy, labor, and the puerperal state. The subject was fully discussed under various headings. As an agent for the induction of premature labor, Dr. Phillips concluded that it was not reliable. It was of use during the dilating and expulsive stages of labor to increase and intensify the pains, being more certain than ergot and with none of the ill effects of the latter. Cases of simple uterine inertia were the most suitable for its administration. Pilocarpine was useless post partum and to stay hemorrhage. The results of thirty-nine published cases of puerperal eclampsia were given in a table, showing recovery of thirty-one mothers and eight maternal deaths. Good effects were produced by the drug in twenty-eight cases, but in nine such dangerous symptoms manifested themselves that the author said he felt bound to warn others against its use, especially when coma was pronounced. He recommended bleeding in conjunction with pilocarpine where it would not act alone. Dr. Herman did not agree with Dr. Phillips' estimate of the value of pilocarpine in the dilating and expulsive stages of labor, and thought it inferior to ergot. He concurred with the author in his warning against pilocarpine when eclampsia with coma had set in, on the ground of the dangerous liability to filling of the bronchial tubes with secretion. In eclamptic patients who recovered from convulsions and coma, the great danger was from pulmonary complications resulting from the great congestion of the lungs during the fits, and Dr. Herman thought that the liability to these lung troubles would be increased by pilocarpine. Dr. Dyce Brown was struck with the uncertainty of the action of pilocarpine as an ecbolic. Dr. Phillips said, in reply, that he had undertaken his researches with impartiality. He laid especial stress on the danger of using pilocarpine in puerperal eclampsia, a matter which had not received sufficient attention. Sänger's idea, that its use might supersede the forceps, was chimerical, and should not be entertained for a moment. He was sorry that all his evidence pointed to the fact that pilocarpine was not desirable as an ecbolic.

The medical case of the late Emperor Frederick continues to occupy public attention to an unwonted degree. No translation of the German physicians' account of the emperor's illness has as yet appeared in this country, Sir Morell Mackenzie having threatened to institute libel proceedings against any publisher who should venture to produce the work. A summary of their account of the case appears, however, in this week's *British Medical Journal*, and although it is followed by an abstract of Sir Morell Mackenzie's reply, as given in his work on the subject now in the press, it must be admitted that some of the accusations made are sufficiently damaging. The German physicians do not hesitate to charge him with deceit, with gross unprofessional conduct, and, on at least one occasion, with actual want of skill in the performance of intra-laryngeal operations, he having (according to them) then actually seized and crushed the healthy right vocal cord instead of attacking the morbid growth on the left. Sir Morell Mackenzie retaliates with accusations of want of skill on the part of the Germans, and contemptuously dismisses the evidence of some of them as that of discredited rivals. The subject of the quarrel has crept into the lay press, in which, however, only extracts from Sir Morell Mackenzie's forthcoming defence are given, the German version of the case being ignored. In a leading article in this morning's issue, *The Standard*, while not attempting to decide or discuss the professional questions involved, deplores the controversy and regrets that so many recriminations have been indulged in on both sides.

It is an open secret that for some years past there has been considerable friction between the authorities of Owens College, Manchester, and those of the Manchester Royal Infirmary. Some of the most distinguished students of the college have been refused appointments at the infirmary, and during the past summer great umbrage has been given to the staff of the infirmary by electing an Edinburgh surgeon to the professorship of surgery in Owens College, thus completely passing over the surgeons on the staff of the infirmary. It has been suggested that the college would be able to conduct its medical teaching more efficiently if it had a hospital of its own, and it has frequently been stated that Manchester is deficient in hospital accommodation. It is, therefore, a matter for congratulation that the trustees of the late Sir Joseph Whitworth have offered to expend a sum equal to about four hundred and fifty thousand dollars to erect and partially endow a hospital of one hundred and twenty beds in immediate proximity to the college. As the Royal Infirmary is at some distance from the college, the new hospital would be of incalculable value for clinical study to the students of Owens College, and it cannot be doubted that the munificent offer will be thankfully accepted. If erected, the management of the new hospital is to be placed in the hands of the trustees of the college.

Rumors are again afloat that the Army Medical School at Netley is to be abolished. Some months ago it was mooted that the special courses of instruction for the Indian medical service given at Netley were to be discontinued, and it was intimated that the Government were considering the advisability of giving special instruction to young medical officers on arrival in India. There are obvious objections to such a course, and it is sincerely to be hoped that the school at Netley may be preserved in its integrity both for army and Indian medical officers.

OUR PARIS LETTER.

PUERPERAL SEPTICÆMIA—URINE AFTER INTERMITTENT FEVER—ABDOMINAL NEPHRECTOMY.

PARIS, October 12, 1888.

In support of his candidature for the Membership of the Academy of Medicine, Dr. E. Verrier, a well-known obstetrician, made the following communication on the treatment of puerperal septicæmia, founding his observations on a case that had lately come under his notice. It was that of a woman in confinement, and in whom, after the birth of the child, the placenta was retained and adherent to the right horn of the uterus. After numerous manual attempts, the medical attendant succeeded in extracting only about two-thirds of the placenta, including the membranes and the umbilical cord. Owing to the extreme fatigue of the patient, instead of the operation of "curetage," or cleansing of the womb, Dr. Verrier, who was called in, recommended intra-uterine injections with a solution of corrosive sublimate of one to two thousand parts. At the commencement all went on well, but on the fifth day the first symptoms of puerperal septicæmia manifested themselves, the general state of the patient became aggravated, and there was a notable rising of the temperature. On the ninth day, the septicæmia having become more accentuated, the injections of the sublimate were replaced by injections of a two per cent. solution of carbolic acid. At the same time alcoholic drinks were administered to the patient. From this moment the state of the patient improved, and on the twentieth day after her delivery, with the exception of a phlebitis in the right leg, she might have been considered as cured. Dr. Verrier concludes from this case that in the gravest forms of putrid infection, after forced abandonment of a portion of the placenta, strong antiseptic injections, frequently repeated, suffice to rid the patient of the placental débris which could not be extracted, and to render aseptic those which remained adherent. It is, therefore, not necessary, in the very great majority of cases, to subject the womb of the patient to the further traumatism to which it would be exposed by the operation of curetage or scovelling.

Some time ago Professor Verneuil made some researches on the condition of the urinary excretion after intermittent fever. He found that a great number of patients suffering from that affection became diabetic. Dr. Mossé, of Montpellier, undertook to verify this point of urology in all the paludal patients of the hospital of Montpellier. At first his results were entirely negative; later on, since 1881, when his first researches were published, to last year, he established, of about one hundred cases of paludism, only 2 cases of glycosuria, and even in these two cases it occurred to individuals predisposed to this accident; one was a wet nurse, and the other an "arthritic" subject. Dr. Mossé, however, found that if glycosuria was rare consecutively to an access of impaludism, polyuria, on the contrary, was rather common a few days after febrile paroxysms. These observations were communicated through Professor Bouchard to the Academy of Medicine last week. At its meeting of the present week, Professor Verneuil, in responding to Dr. Mossé's observations, stated that he did not wish to attack the negative results which Dr. Mossé had made known. But he did not believe that these results can be generalized. That which is true for the South of France or for Algiers may not be true for hot climates. Several employés of the Company of Panama were sent to M. Verneuil, as the doctors there had recognized in them the existence of diabetes after paroxysms of intermittent fever. He had also learned from a medical officer at Bombay that glycosuria was frequent in impaludal patients in that Presidency, and in other tropical countries. Professor Verneuil is of opinion that paludal glycosuria is met with more particularly in regions where hepatism is endemic, and perhaps it is not met with elsewhere. In any case, to judge the question impartially, new researches carried out in divers points of the globe should be awaited.

Dr. Terrillon reported the case of a woman, aged thirty years, on whom he had performed abdominal nephrectomy, for a displaced suppurating and tuberculous kidney. The patient had for seven years experienced severe pains in the region of the right kidney, but principally in front of and below the liver. At the same time she noticed the existence, in the flank of the same side, of a tumor which was looked upon as a displaced kidney. An incision was made, extending from the borders of the ribs to the crest of the ilium. In the attempt to remove the kidney it was found difficult to do so with its capsule, and the surgeon had to remove it by piecemeal. It was, however, found necessary to leave a small stump at the bottom of the cortical portion of the kidney. The edges of the capsule of the kidney were fixed to the abdominal opening, and the capsule itself was filled with iodoformed gauze. The fragments of the kidney that were removed were found to be the seat of tuberculous lesions in every stage of evolution. The operation was crowned with success. A fistula which had remained soon disappeared, and the patient may now be considered completely cured.

Dr. Chibret, of Clermont-Ferrand, has performed experiments with three antiseptic agents on the pyogenic "micrococcus aureus," and the following were the results obtained: The oxycyanide of mercury at $\frac{1}{1300}$ acts like the sublimate at $\frac{1}{1400}$; that the cyanide does not act so well as the oxycyanide; that the solutions at $\frac{1}{100}$ of the oxycyanide, of the cyanide, and of the sublimate killed the aureus in five minutes; that the same solutions at $\frac{1}{1000}$ kill it in less than an hour; that the same solutions at $\frac{1}{3000}$ commence to kill it only at the end of four hours, and that cultures of the aureus may survive even after ten hours. Employed in surgery, on suppurating surfaces, or to render mucous membranes aseptic, and particularly the conjunctiva, the solution of the oxycyanide of mercury at $\frac{1}{1500}$ procures an asepsy superior to that which is obtained by the sublimate, owing as much to the tolerance of the tissues as to the feeble absorption.

INFLAMMATION OF THE SEMINAL VESICLES.

To the Editor of The Medical Record.

Sir: Permit me to correct several errors in your abstract (September 15th) of the paper read by me at the meeting of the British Medical Association. I do not find "pain in defecation, and constitutional disturbance" are leading symptoms. Supra-pubic pain of moderate intensity, increasing as the bladder distends and being relieved by urination, is usually prevalent. I am reported to have said that suppuration of, or about, a vesicle should be incised into from the rectum; now that is just the very thing I protested against. All suppurations between the bladder and the bowel should be opened from the perineum.

My paper will appear in full, in due course, in the pages of the *British Medical Journal*.

May I say in conclusion that, if surgeons will direct their attention to this class of maladies a little more carefully, the majority of the late gonorrhœal obscurities which puzzle them will become intelligible.

I am faithfully yours,
Jordan Lloyd, M.D., F.R.C.S.

Birmingham, England,
September 26, 1888.

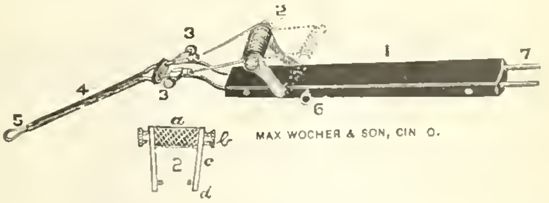
New Instruments.

A NEW GALVANO-CAUTERY HANDLE.

By MAX THORNER, M.D.,

CINCINNATI, O.

I present to the notice of the profession some modifications in a Galvano-cautery Handle, the essential points for which I claim novelty being its simplicity and availability. The handle consists of the usual hard rubber handhold (1). The interrupting button (6) is placed on the side, similar to others now in use. In the use of snares the draw-tubes (4) are inserted into grooved slots, fixed by two set-screws (3). The wire, at its free ends, is attached to two buttons on the side of a simple swing-lever (2), the latter consisting of an isolating bar of hard rubber (fig. 2, a), from which two steel spring-bars (c) pass downward, and are attached to the body of the handle by two small prongs (d) fitting into notches.



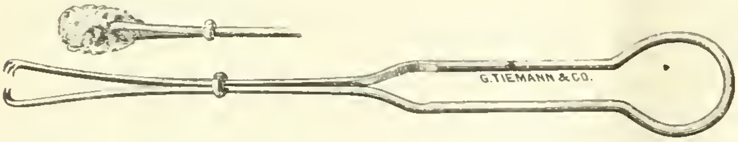
The index-finger of the operator is placed on the hard rubber bar, the latter being roughened to prevent slipping, while the thumb presses on the interrupting-button, giving full control of the circuit. The wire is drawn home by simple flexion of the index-finger, swinging the lever back. This backward movement of the lever gives the operator absolute control of the snare, allowing of rapid or slow traction, as desired.

To change snares, or to use simple electrodes, it only requires the loosening of the wires from their attachment and unscrewing the set-screws, when the snare can be readily lifted out. The lever swung back makes an excellent finger-rest for the index-finger when using the knife or similar electrodes. If desired, the whole lever, with the snare attached to it, may be lifted out of the notches.

AN IMPROVED SPONGE-HOLDER.

By F. C. HUSSON, M.D.,
NEW YORK.

I WOULD like to call the attention of the profession to an easily cleaned and perfectly aseptic sponge-holder, which was made for me in Paris, and which can now be obtained from Messrs. George Tiemann & Co., in this city.



The instrument is nine inches long, and made out of a single piece of steel wire, nickel-plated. The blades are brought together by an incomplete ring of steel, which can be readily slipped off, thus permitting the instrument to be thoroughly cleaned.

The woodcut represents the instrument so clearly that further explanation is unnecessary.

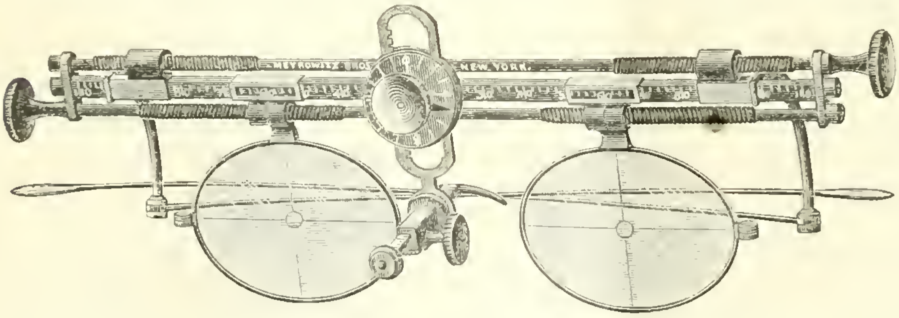
The advantages that I claim for this instrument are: 1. That it is easily cleaned, hence thoroughly aseptic. 2. That it is light, strong, and durable. 3. That it is cheap.

111 EAST TWENTY-THIRD STREET.

ADJUSTABLE FRAMES FOR TAKING FACIAL MEASUREMENTS.

By C. H. FISHER, M.D.,
SCRANTON, PA.

THIS apparatus is practically a pair of mechanical spectacles, so constructed that the four principal measurements required in the ordering of spectacles are easily obtained. The eyes hold a pair of plane lenses on which the centres are marked by cross lines. These are adjusted to the pupils, and the distance between them read in millimetres on the sliding bar above; the distance between temples is measured by means of a pair of adjustable bows, and registered on the same bar. The measurement of the nose is accomplished by two independent mechanical movements, up and down, and in and out, both by means of rack and pinion, as shown in the engraving, both measurements being registered by scales which are easily read.



In fitting glasses it is scarcely less necessary that the frames should be perfect, than that the lenses should correct the refractive error. Much difficulty has heretofore been experienced, by those ordering glasses from a distance, to give the proper measurements with the instruments ordinarily at hand.

By means of these trial frames the tyro can succeed in getting a perfect fit as well as the most experienced oculist. The entire instrument is light and of superior workmanship, and will be found invaluable by those ordering from a distance.

I am indebted for some valuable assistance in the mechanical construction of the instrument to Messrs. Myrowitz Brothers.

A FLEXIBLE SCALPEL.

By A. W. P. LEUF, M.D.,
OF THE UNIVERSITY OF PENNSYLVANIA, PHILADELPHIA.

FULLY seven years ago, while demonstrating in the dissecting-room of the Long Island College Hospital, Brooklyn, and winter before last, while performing the same duties at Dr. George McClellan's Pennsylvania School of Anatomy and Surgery, and during the entire seven years gone by, I have had in use a scalpel which for neatness of work, ease of sharpening, and satisfaction in handling, is decidedly superior to any other knife that I have ever seen. The scalpel is made of the best steel, and so thin that it is very flexible. The advantage of flexibility is the facility with which it adapts itself to curves; for instance, in dissecting away the skin it can be laid almost flat upon the integument and drawn along with a steady sweeping motion, cutting the connective tissue so close to the skin as to render the work of the neatest kind. It can be laid against muscles, bones, nerves, blood-vessels, and some of the viscera, and made to adapt itself to curves and bends. At first its flexibility may seem a little awkward, though it soon is controlled, and then the dissector realizes that he has in his hand an instrument that enables him to be more neat and rapid in execution than with any other knife he can handle.

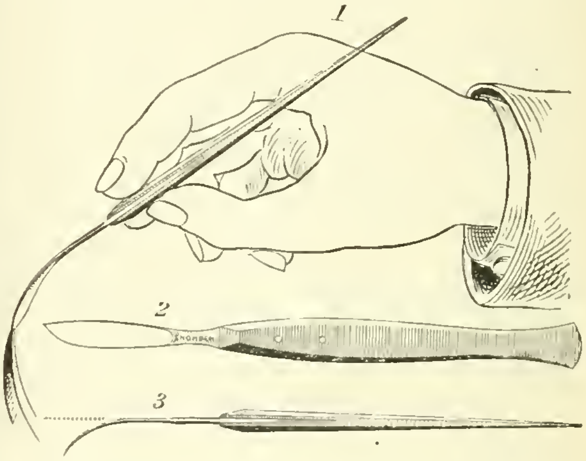


Figure 1 shows the knife in making an upward and outward stroke; just enough force and pressure is being made to bend it as shown in the cut. If the direction of the cut is in line with the plane of the blade, and kept so, as much force as necessary can be employed for all ordinary dissecting. In some heavy work it cannot, of course, supplant the ordinary scalpel, but it is a necessity in every good case of dissecting instruments. Figure 2 shows that the blade has the same shape as any other scalpel; while Figure 3 shows the blade edgewise and bent away from the straight line, but to which it immediately returns when the pressure is removed.

I feel confident that the flexible scalpel is a useful instrument, and that it will be so judged by all who give it a trial. Green hands can do much better work with it than they can with the ordinary stiff instrument.

Its thinness makes a sharp edge an easy possibility. Every ten or fifteen minutes it can be lightly drawn a few times across the edge of a stone or board, or across the shoe, and made as sharp as ever.

Mr. W. Snowden, the well-known instrument maker of Philadelphia, is the manufacturer of these scalpels.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from October 14 *to October* 20, 1888.

Page, Charles, Colonel and Assistant Surgeon-General, Medical Director of the Department. Will proceed to and inspect the Medical Department at Forts Ellis, Tex.; Supply, Reno, Sill, and Gibson, I. Ter.; Fort Leavenworth, Kan., and the Leavenworth Military Prison, in the order named, and upon completion of this duty return to these Headquarters. Par. 1, S. O. 127, Headquarters Department of the Missouri, Fort Leavenworth, Kan., October 15, 1888.

Comegys, Edward T., Captain and Assistant Surgeon. Relieved from duty at Madison Barracks, New York, and will report in person to commanding officer, Fort Bayard, N. M., for duty at that post, relieving First Lieutenant William D. Dietz, assistant surgeon.

Munday, Benjamin, Captain and Assistant Surgeon. Relieved from duty at Jefferson Barracks, Mo., and will report in person to the commanding officer, Fort Sisseton, Dak., for duty at that post, relieving First Lieutenant John L. Phillips, assistant surgeon, and reporting by letter to the commanding general, Department of Dakota. Par. 11, S. O. 242, A. G. O., Washington, D. C., October 17, 1888.

Dietz, William D., First Lieutenant and Assistant Surgeon. On being relieved by Captain Comegys, will report in person to commanding officer, Alcatraz Island, Cal., for duty at that post, reporting by letter to the commanding general, Department of California. Par. 18, S. O. 240, A. G. O., Washington, October 15, 1888.

By direction of the Secretary of War the following-named officers of the Medical Department will report in person, on October 23, 1888, to the President of the Army Medical Examining Board, Army Building, New York City, for examination for promotion: Captain **John de B. W. Gardiner**, assistant surgeon; Captain **William C. Gorgas**, assistant surgeon; Captain **C. N. Berkeley Macauley**, assistant surgeon; First Lieutenant **W. L. Kneedler**, assistant surgeon; First Lieutenant **Edgar A. Mearns**, assistant surgeon. Upon the completion of their examination the officers named will rejoin their proper stations. Par. 1, S. O. 239, A. G. O., Washington, D. C., October 13, 1888.

Phillips, John L., First Lieutenant and Assistant Surgeon. On being relieved by Captain Munday, will report in person to the commanding officer, Fort Lyon, Col., for duty at that post, reporting by letter to the commanding general, Department of the Missouri. Par. 11, S. O. 242, A. G. O., Washington, D. C., October 17, 1888.

Official List of Changes in the Medical Corps of the United States Navy for the week ending October 20, 1888.

Magruder, A. F., Surgeon. Ordered to the Marine Barracks, Washington, D. C.

Stone, E. P., Assistant Surgeon. Detached from the Richmond and ordered to the Minnesota.

Keeney, J. F., Assistant Surgeon. Detached from the Minnesota and ordered to the Richmond.

McCormick, A. M. D., Assistant Surgeon. Detached from the Bureau of Medicine and Surgery and ordered to the Vermont.

Moore, A. M., Surgeon. Detached from Naval Station, New London, Conn., and ordered to the Kearsarge.

Austin, A. A., Passed Assistant Surgeon. Ordered to Naval Station, New London, Conn.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 20, 1888:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	47	13
Scarlet fever	84	15
Cerebro-spinal meningitis	1	1
Measles	72	8
Diphtheria	64	19
Small-pox	1	0
Yellow fever	0	0
Cholera	0	0

The History of Yellow Fever.—Mr. Kirk Munroe has given, in the *New York Times*, a very condensed summary of the history of yellow-fever epidemics. Although the home of yellow fever is in the West Indies, it has become naturalized in the United States, where it has existed in a more or less active form for nearly two centuries. It has never appeared in Asia, Australia, the islands of the Pacific, nor, so far as is known, in Africa, and it has only been felt sporadically on the Pacific coast of North and South America. In Europe it has invaded Spain, Portugal, Italy, France, and England. In South America it has prevailed in British Guiana, Columbia, Peru, Bolivia, Brazil, and the Argentine Republic. In North America it has ravaged Honduras, Mexico, and the West Indies, and has even appeared so far north as Quebec. Of the United States the following have suffered from its visitations: Maine, New Hampshire, Vermont, Massachusetts, Rhode Island, Connecticut, New York, New Jersey, Pennsylvania, Delaware, Maryland, Virginia, West Virginia, North Carolina, South Carolina, Georgia, Florida, Alabama, Mississippi, Louisiana, Texas, Kentucky, Tennessee, Missouri, Arkansas, Ohio, Indiana, Illinois, and also the Indian Territory. The first authentic record of its appearance is in Central America in 1596, and its most terrible visitation was that to the island of St. Lucia in 1666, when it swept away every soul of a population of 5,000. It first appeared in New York in 1668, in Boston in 1691, and again in 1693. Philadelphia was first visited in 1695, and again in 1699, when the city was but seventeen years old, it swept away 220 of its scanty population. In this year also it first appeared in Charleston, S. C. In 1702 it raged with great fury in New York until the 30th of September, the mortality reaching 570, and in that year it first visited the Gulf coast, appearing at Biloxi, Miss. In 1705 it visited Mobile, and also made its first appearance in Europe, at Cadiz, Spain. Between this date and 1800 it appeared in Charleston, S. C., 17 times, in New York 16 times, in Philadelphia 12 times, in Baltimore 5 times, in Boston 3 times, and in New Orleans 4 times. Prior to the year 1800 it also visited such remote places as the island of Nantucket, where, in 1763, 259 persons died from it; Catskill, N. Y.; Hartford, Conn., Portsmouth, N. H., Albany and Greenfield, N. Y., Salem, Mass.. and Woodbury, N. J. In this country the most terrible visitation in the last century was in 1798, when the mortality from yellow fever in Philadelphia was 3,500, in New York 2,080, in Baltimore 200, in Wilmington, Del., 225, in Portsmouth, N.

H., 100. in New London, Conn., 81, and in Chester, Penn., 50. In this year also, on the island of San Domingo, out of 25,000 troops the incredible number of 21,190 fell before the dread destroyer. In 1799 the death list in Philadelphia from yellow fever reached 1,000, and in New York 76 During the year 1800 the most terrible ravages of the fever were confined to Spain, where, in Cadiz, the cases numbered 48,520, and the deaths 7,387; in Xeres, with a population of 33,000. the cases numbered 30,000 and the deaths 13,000; in Seville, with a population of 80,568, the recorded cases reached the enormous number of 76,488 and the deaths 14,685. Many other smaller Spanish cities suffered in like proportion, and in Havana the mortality was 9,977. In this year also New Bedford, Providence, Hartford, Boston, New York, Philadelphia, and other Northern cities suffered more or less, and in Norfolk, Va., the fever claimed 250 victims out of nearly a thousand cases. In 1801 Spain and the West Indies again suffered. and the fever spread into Italy, where, at Leghorn, 150 died daily for several months. It also visited several places in the United States, among them Block Island and Queensborough, in Orange County, N. Y., where 140 persons died during the month of October. In 1802 the mortality from yellow fever in the West Indies was something frightful. In San Domingo there were 27,000 cases and 20,000 deaths, and other islands suffered in like proportion. In 1803 the fever began in New York on July 18th, and ended in October, with a death list of 6,700 souls. In 1804 Cartagena, Spain. lost from yellow fever 14,940 of her population of 32,220, and Malaga from a population of 36,000 lost 11,464. The official reports of deaths from yellow fever in Spain for this year place the mortality at 124,000, and the population of the country is said to have been reduced by more than a million. In 1805 Quebec was visited by the fever for the first and last time. The attack was of short duration, being nipped by frost early in September, but it was so severe that out of one company of English troops, 55 in number, all perished except 6. In this year also the fever again raged in Philadelphia, destroying 3.400 persons. From this date until 1819 there was no epidemic of yellow fever in the United States, though every year witnessed a number of sporadic cases. In 1819 it broke out in Alabama and Louisiana, and in New Orleans the mortality was 2,190. Spain suffered terribly during this year and in the two following. In 1822 New York witnessed its last epidemic of the fever, where out of 414 cases 230 died. Since this date there have been no epidemics of the fever on the Atlantic coast north of Norfolk, Va., though a number of imported cases scattered about the shores of New York Harbor threatened to cause one in 1856. The terrible epidemic of 1853 that swept over portions of Florida, Alabama, Mississippi. Louisiana, Texas. and Arkansas, numbered its victims by thousands. In New Orleans alone during the month of August the mortality was 6,235, while before the epidemic ended the death list had swelled to a total of 8,400. In 1854 the dread fever claimed 2,423 more victims in New Orleans, and in 1855 2,670. In the latter year the pestilence also raged in Norfolk, Va., where it claimed 1,807 victims, and in Portsmouth, Va., where the mortality was 1,000. In 1857 Jacksonville, Fla., was visited for the first time. In 1858 the mortality in New Orleans was 3,889. A phenomenal year was 1861, when not a single case was reported from any quarter of the United States. This was probably owing to the all-absorbing interest of the war. After 1853 the next great epidemic year was 1867, when the principal sufferers were Louisiana and Texas. During this season the mortality in New Orleans reached 3,093; in Galveston, Tex., 1,150, and Memphis, Tenn., 231. In 1870 there were 49 deaths from yellow fever on Governor's Island, in New York Harbor, and 18 in Philadelphia. but in neither case did the fever spread beyond its original limits. Florida, and Charleston, S. C., suffered in 1871, and in 1873 another great epidemic of yellow fever swept along the Gulf coast and up the Mississippi Valley, touching parts of Florida, Georgia, Alabama, Mississippi, Louisiana, Texas, Arkansas, Tennessee, Kentucky, Illinois, and Ohio. The greatest mortality was at Memphis, where it reached 2,000. In 1876 the yellow fever became epidemic in Savannah, Ga., and in 1878 occurred the most terrible epidemic of the disease yet known to this country. It swept along the Gulf coast and up the valley of the Mississippi to Cairo, Ill., seizing its victims in every city, town, and almost every village and plantation in its course. So malignant was it that it readily attacked domestic animals, and even the wild deer of the forest are said to have died from it. In Memphis, with a population reduced to less than 20,000, there were 17,600 cases and 5,150 deaths, a ratio of mortality to cases of 1 in 3.3. Since that awful time to the present, a period of ten years, there have been no great epidemics of the pestilence in this country.

An Interview with the Late Dr. Fothergill.—It was at one of these meetings that the lecturer introduced me to Dr. J. Milner Fothergill. whom I had been prepared to meet by the somewhat graphic description I had heard, and which portrayed him as being a "bag of wind as big as a bed-tick." Certainly not very elegantly put. An American would probably have said that he "played with a long bow." Dr. Fothergill is the "biggest" doctor I met while abroad. I think he will weigh upward of two hundred and fifty pounds. He is unwieldy in appearance and lacks all the graces of Apollo. No sooner was he told that I was from the States than he professed the greatest admiration for the Yankee. He spoke highly of Bartholow and DaCosta—said Flint was a fine diagnostician but a poor therapeutist. That he (Flint) could not treat him (Fothergill) for the State of New York. Dr. Brunton's Letsomian Lectures were on Digestion, Indigestion and its Treatment—a subject, as you all know, upon which Fothergill has written a book. I remarked to him that I had been greatly interested in his work on "Indigestion and Biliousness." "Ah!" said he, "if you have read my book carefully, you are prepared, all the more, to fully appreciate Brunton, for the more knowledge you bring to the subject the more you will enjoy him." "Do you know," said he, "that Brunton and myself are the hardest workers in London?" I said I supposed so. "Oh, but he is by far the cleverer fellow of the two. you know." I am afraid I said that I didn't know. "But he is not as practical as I am, he *cannot turn a sentence* as I can, you know. But I did not attain this excellence of style without large reading and hard work—haven't I sweat though?" And from the way he was then puffing I could easily imagine he had—but I only observed that the thorough mastery of his subject was not more impressive than the lucidity and elegance of his style. "It is a great help to an author," said he, "it enables him to give finishing touches to his work, as an artist to his picture."—Dr. H. B. Lowry, in *Omaha Clinic*.

Treatment by Suppressing Menstruation.— Dr. Loewenthal, in the *Rev. Obstet. et Gynecol.*, reports the results of treating twenty-three patients suffering from chlorosis or hysteria by suppressing the menses. The method employed consisted in injections of hot water of the temperature of at least 49° C., with complete rest in bed. In some very rare cases iced water was employed preferably to hot water. In eighteen cases the remedy was employed for pure chlorosis. The five others comprised two cases of grave hysteria, and three of convalescence from exhausting maladies. In these latter the convalescence was shortened. One of the hysterical patients received a marked advantage, and all the chlorotics were cured with surprising rapidity, and without ulterior medication, after from three to five menstrual suppressions. No grave consequences were noted.—*Journal of the American Medical Association.*

INTERPLEURAL PATHOLOGICAL PRODUCTS: THEIR CAUSE, SIGNIFICANCE, AND SPECIFIC RELATIONSHIP TO PULMONARY PHTHISIS.

By J. R. LEAMING, M.D.,

NEW YORK.

THE normal healthful pleuræ are free in movement. Their surfaces glide over each other in respiration without sound-producing friction. They cover the lungs and their lobes, the inner costal walls of the chest, the outer surface of the pericardial sac, and the mediastinum. They are not only smooth of themselves, but they are lubricated by a natural secretion never in excess and never absent.

Unfortunately, the normal healthful condition of the pleuræ is not what is most frequently found in post-mortem examinations, for seldom are the pleuræ entirely free from pathological results. The early pathologists, finding these conditions of such frequency and without history of illness as cause, looked upon them as normal. It is not yet twenty years since Doctor Flint, standing in the very front of medical renown, whose memory we revere and of whose fame we are proud, in leading the discussion of a paper on pleuritis which I had the honor of reading before the New York Academy of Medicine, said, in effect, and not unkindly, that the profession would not agree with me in my estimation of the causes, pathology, physical signs, or treatment of interpleural adhesions; that they were not discoverable by auscultation, had no effect upon the health of the individual, and could not be reached by medication. There is no doubt that Professor Flint truthfully represented the verdict that would have been given by the profession throughout the world, could it have been taken, at that time. But since then, many advanced pathologists have adopted other views. Sir Andrew Clark, especially in his Lumleian lectures of three years ago last spring, gave a very thorough and clear account of interpleural pathological products, without acknowledgment of any American assistance. My early connection with this subject, if I am not, indeed, the earliest one to draw attention to it, is, I suppose, the reason that I have been invited to bring it before you at this time.

Laennec and Louis refer to saddle-leather creaking sounds as being due to old cartilaginous adhesions within the pleuræ. But all other râles and rhonchi were believed to be interpulmonary or interbronchial. But the application of the laws of sound points out unerringly their location and mechanism, and furnishes the elements of a correct diagnosis

Pathological products within the pleuræ are foreign elements, whether they are growths, like cancer, or benign tumors, tubercle, or other neoplasms; or whether they are exudates, the result of inflammations, or of depressed vitality—of which I shall have much to say in this article.

Of tumors or neoplasms, benign or malignant, I shall not discourse, not intending to be exhaustive of the subject of interpleural pathology, but shall confine myself to the two forms of exudates—sthenic and asthenic, which may influence or cause phthisis pulmonalis.

The interpleural exudates which interest us in this discussion are of two kinds: First, those which are the result of active inflammation, such as pleuritis or pleuropneumonia; second, those which result from depressed organic life. The first is the one generally had reference to when the subject is under consideration.

At the discussion which followed the very able papers before the New York Academy of Medicine, led by Dr. Westbrook, on the subject of interpleural exudations as cause of consumption, the sthenic was the only form considered. It depresses the organic life by its mechanical pressure, pressing upon the organs, shutting off the circulation by closing capillaries for nutrition and for aeration of the blood in the lungs. There is more or less natural tendency to remove this foreign factor by the absorbents, and the effort is successful or not according to the degree of vigor of organic life in the body.

There is no question that they depress the vital force mechanically; but they have no other phthisical tendency. Such seemed to be the apprehension of this subject by the New York Academy of Medicine. But there is another cause producing exudation within the pleuræ which is not preceded by inflammation or the rise of temperature. Indeed, many times the temperature is subnormal before and at the time of its exudation, and soon commences to contract, and the temperature to rise, or to vacillate from below to above the normal. This cause is within the life of the individual, is a part of it, and is immaterial; while the first causes are exterior to the life and are material. There is a trinity of life in man: The organic; the intellectual; the moral or responsible.

Life, like heat and electricity, is known only by its manifestations. Let us study the beginning of these manifestations of organic life, as Harvey did with the eggs of the hen during incubation. After the first day, upon opening the shell, it was found that the relative positions were changed—of the yolk, the white, and the germinal spot or eye, and that the white began to be a little turbid. This was the first manifestation, and proved that the hen had been with the cock, for the eggs of the hen which had not been with the cock did not show these changes. In them were no manifestations of life, and there was no life, for an unfertilized egg is dead. In the fertilized egg before incubation the life is inchoate, and by incubation it is warmed into manifestations. At the end of the second day the changes are still more marked, and at about the beginning of the third day a little point of red appears in the germinal spot, pulsating. This is the beginning of the circulation of the blood before there is a heart, proving that the rhythm and pulsations are primal manifestations of organic life, which then commences to build—first the right auricle and ventricle, and afterward the left heart. Finally, the arteries still shooting out, the whole body is formed in completeness. This organic life—the builder, is immaterial. It uses the prepared organism of the egg as the mason does the brick and mortar, the stones and cement provided for him. It shapes the building in form and for use.

The immaterial essence which results from sexual congress, and which builds the material body, preserves its identity as an individual from the moment of conception until its final death, or until its manifestations cease in the material world. But as organic life always manifests itself in form, as well as in motion, we see the spermatozoa of the male with its distinctive form and locomotion by which it reaches the ovum of the female and is destroyed and a new creature begun.

In the fable of Dionysius or creation, representing in Greek mythology desire or love—"Semele, Jupiter's paramour, made him take an inviolable oath to grant her one wish, whatever it might be, and then prayed that he would come to her in the same shape in which he was used to come to Juno. The consequence was that she was scorched to death in his embrace."

The form of the individual continues during life, modified by age, accident, or disease—also the form of the organs, the members, and the constituent parts, the blood-disks, the cells of all the tissues, and the secretions. Everything that has life has inherited its form, its limit of age, and transmits the same to its children—not only the essential inherent qualities of the individual but, many times, acquired peculiarities. So that disease forms and tendencies may also be inherited—not the material, but the immaterial.

The building material in each individual is introduced into the blood from the digestive organs, and is vivified and used to build or repair the form, which, as it grows old and dies, is thrown out of the system, and fresh, new material takes its place. The life and form continue, and are continually modified by time until the limit of the age of the individual is reached, when formation ceases and form decays. The most absolute proof of the immateriality of life is its death ; because the dead body is proof of its former life. The excellence of Lord Byron's beautiful simile in "The Giaour," in the description of "Greece, but living Greece no more," depends upon the appearance of form simulating life :

> Before decay's effacing fingers
> Have swept the lines where beauty lingers.

Bone is the evidence of the once living animal. *Hamlet*, with Yorick's skull in his hand, reasons upon the former life of its occupant until his "gorge rises," and he puts it down in disgust, but goes on in his illustration by citing the dust of Alexander and that of Cæsar in decay, and suggests the vile uses to which they might come. Wood is the evidence of the life of the tree, and of its growth from the seed ; the identity of the life remaining ever, for the wood was always cedar, mahogany, or oak, as was the seed from which it sprang. The life remained, although it often changed particles—the particles which it took up from the ground and assimilated always making cedar, mahogany, or oak, never losing identity, for a thousand years or more, a continual evidence of the immateriality of life in the tree as in the animal. And the wood remains the death-evidence of the life of the tree for thousands of years afterward.

The diamond, the ruby, or the sapphire are evidence of the immaterial Creator. "The earth was without form and void." Divine creative energy flashed through these elements and crystallized them into gems of particular form, brilliancy, and hardness, or of rocks enduring, or of ores of precious metals, where they ever remain evidence of the eternal immaterial existence of the Creator. The crystal, the tree, the animal, represent the primal creation.

Man is mortal—the race immortal. There is an endless succession of individuals, each filling his allotted time and then giving way for his successor. Each constituent molecule is mortal, like the individual man. It has its limited time of existence, and then passes away and gives place to a new one—and the succession goes on during the existence of the individual. It has its predecessor and successor, and with them its acquired tendencies to disease. These are laws impressed upon all organic life—heredity and endless succession. The organic life, besides pervading every constituent part of the body, has its particular home in the great sympathetic nerve. A connected series of ganglia near vital regions massed together in plexuses are reservoirs ; each ganglia, however, is, in a measure, independent, yet all are joined in sympathy with each other, and with the unity of the individual. Filaments accompany each artery, vein, and capillary. The organs of special sense, the heart, lungs, kidneys, liver, stomach ; of digestion, of secretion, of generation ; even the brain, which itself was created for the home of the intellectual life, is in every part of it supplied with organic life. The brain could not emit a single thought or emotion without the active assistance of organic life. We learn of the intellectual life through its manifestations. The feeblest brain-effort of the newt to the highest development of man are recognized only by their manifestations. Both seek their food, defend themselves from danger and attack, and propagate their kind. Their intelligence differs with corresponding differences of brain-development. The chief manifestations of the lower animals are locomotion with definite purpose. In man the manifestations are of greater extent and greater power, with the capacity for improvement by education. But what distinguishes man from all other animals is a manifestation of another kind of life—a moral life, or conscience The manifestations of this new life may be very feeble, but they are distinct, and admit of education, like the intelligence. It is quite certain that each may be educated separately or in unison ; but, if separately, resulting in a moral monstrosity. The trinity of life in man may be thus stated : First, the organic (the builder)—the life of the body ; second, the intelligence—the life of the soul ; third, the conscience—the life of the spirit ; body, soul, and spirit all immaterial—each known by its manifestations only. The evidence of the immateriality of the life of the body is in its manifestations otherwise as builder. We could know nothing of them but by building the form of the material body in all its parts, and as a whole ; its mysterious conception—intra-uterine existence, and birth, and independent life through the periods of infancy, childhood, youth, manhood, old age, and natural death. Intellectual life commences after birth, noticing outside objects, learning its relationship to the outside world, feeling pain, showing pleasure, fear, or joy. The manifestations increase with the growth of the body and the successive stages of periods of age, until decline and death. The soul, too, grows old. Its habitation, the brain, is part of the body ; and as the body grows feeble by age, the intellect must give feebler manifestations, according to the waning power of the body, and the brain its instrument.

The manifestations of the spirit commence only when the soul upon which it depends has arrived at some degree of capacity for intelligence. All human laws recognize this fundamental truth, for the child is not held responsible for its acts until it has arrived at the age of discretion. Responsibility is measured by intelligence. Intelligence is limited by the development of the body. This delicate interdependence may become deranged at any time during the life of the individual. It is frequently temporary, as in fevers, or in intoxication from medical agents, or commonly by alcohol ; or may be more or less permanent, as in pathological conditions of the brain, or reflex, in sympathy with organic disease in some other part of the system of organic life. This higher development of the animal in body and soul, with the added form of spirit or moral life, belongs alone to man. "Conscience makes cowards of us all," is an appreciation by the poet of the spirit's power, for good or evil, over the physical organism. It dominates with controlling force in nutrition, in pathological conditions of atoms as observed in the intimate structure and in the blood. This power is in contradistinction with the outside agents which affect the life of the body—such as poison of different varieties brought in contact with the organic life, externally or within ; or miasma, which is simply another form of poison ; or microbe, especially the bacillus tuberculosis. The *modus operandi* of these agents is difficult of explanation, but the practical fact remains that tartarized antimony will cause emesis, or that croton oil will produce catharsis, and that other agents the same or similar effects or different ones, and that we make use of our experimental knowledge of them in the treatment of diseases. Again, it is just as difficult to explain how the *materies morbi* which may come to us in the air which we breathe or in the food we eat—miasmatic or microbic—should always produce in the organism the same diseases. There is nothing *a priori* in the constitution of the *materies medicatrix* or of the *materies morbi* which will explain their peculiar and characteristic effects upon the living organism. We are forced to the conclusion that the peculiarity of the invariable effects of these exterior agents is not in the agents themselves but in the organic life—for if the life has gone out of the body these agents have no similar effect. Calomel or other preparations of mercury applied to the dead body produce no characteristic effects, as they invariably do when applied to the living organism. And so with all other medical agents or poisons, or disease-germs. They are exterior causes which have power to influence the interior life of the body for health or for disease. But the spirit is a potent factor in preserving health or in causing disease, and its action is not more mysterious upon the organic life than is that of the *materies morbi* or the *materies medicatrix*.

This interior cause which dominates the life of the body through the life of the soul, although depending upon them for its life, controls their healthful manifestations when benign, or of disease and death when malign. It may cause death of the body by first causing death of the atoms, instantly or successively. When malignly influencing the atoms, causing their immediate or successive death, it gives rise to diseases of the body similar to those produced by the *materies medicatrix* or *materies morbi*. With the tissues and circulation filled with these dead and diseased atoms, the organic life attempts their expulsion by crowding them through the walls of capillaries into the natural cavities of the body, notably the pleuræ and the cellular tissues. They are not all dead atoms, but diseased, and when thrown out of the systemic circulation they still have vitality left for organization, imperfect as it is. The immediate action of this pseudo and imperfect organization is to contract, and in this manner to cripple the functions and manifestations of the organic life in local areas of the physical body. The pleural cavities are the great dumping-ground of the organic life. Here pathological products are more frequently found, and when of much extent their contraction mechanically closes the capillaries of the lungs upon their surfaces, preventing largely the aeration of the blood, and, all of the malign causes continuing to operate, it becomes progressive fibroid phthisis. The temperature, perhaps, always is subnormal in the earliest stages of exudation. But when contraction commences after adhesions, the local irritation causes the temperature to rise at irregular times, and vacillates from below to above normal. It is frequently a sign of organic feebleness and a losing struggle in the battle of life.

Physical and pathological conditions similar to these followed the severe storm last March in New England and New York, known as the blizzard. It will be remembered that the temperature was low—about zero—and that the winds were very high and the atmosphere loaded with fine particles of ice. The result was, many times, disastrous to those obliged to travel on foot for any length of distance. The exertion was constant and violent; breathing very much interfered with, on account of the fine snow or frost filling the air. This, with the vital depression consequent upon the intense cold, immediately lowered the organic life of the atoms in the circulation, and death or partial death of these constituent parts of the body took place. Soon after the storm—two or three weeks, in some cases—violent efforts of the organic life to expel these dying and dead constituents became demonstrative. Slight or limited attacks of pleuro-pneumonia of a low type, with hemorrhages, became frequent. These were generally amenable to treatment, but the interpleural pathological products increased *pari passu* afterward with vital depression, and many of the sufferers died shortly—that is, within three or four months—with the genuine conditions of fibroid phthisis as from depressed organic life. The method of death was the same as in that of fibroid phthisis from immaterial interior causes; the spirit acting upon the intelligence causing the disease and death of the atoms of the body in the tissues and in the circulation. Great and prolonged sorrow, deep disappointment, worry, and anxiety—the loss of friends and property, of position, reputation—always cause death of molecules, which being crowded out of the circulation, interpleural pathological products occur which may finally result in progressive fibroid phthisis. When this happens to a wife or husband who has unduly and inordinately mourned the other's loss, it has been ascribed, without sufficient reason, to contagion. The known cause of immaterial vital depression through the conscience is enough to account for the morbid phenomena without referring to the principle of contagion, of which we know so little.

I have not known of a case of fibroid phthisis in which a distinct history of vital depression could not be elicited by getting the history of the mental conditions of the patient during the preceding year. Sometimes it comes from great sorrows and anxious worry of a few months. Again, it is the result of years of continual unsuccessful struggle in the battle of life—the inability to cope with its great difficulties. Morbid products accumulate in living organisms. The organic life thrusts them out of its dominion, into the pleural cavity, for instance, where a feeble reorganization takes place, which contracts upon the lungs, shutting off a portion of its circulation and crippling its life-power. Here we may notice the great difference between these pathological products and those which result from the sthenic inflammation. These are characteristic in their morbific results, and in this are distinctive of phthisis pulmonalis. It is progressive—the products are constantly being thrown out into the pleural cavity, until the end. One has an inherent tendency to get well, the other to die, and this needs all the assistance of the physician, or of climate, or of food, to arrest its progress.

Management of fibroid phthisis from interior immaterial causation of molecular death must be rational in order to be successful. The organic life expels the diseased and dead particles, crowding them out of the circulation. The pleural cavities are an ample and the most convenient receptacle. The crowded capillaries of the true respiratory system are separated from them only by the thin membrane of the pleuræ. As might be expected, the pleural cavities give the earliest evidence of morbid impressions upon the individual life of the particles or blood-disks. When the disease is not overwhelming they are thrown out, ejected from the circulation, until the organic life has recovered from the attack, when the mass of débris is taken up by absorbents and carried out of the system. But if the morbific cause continues to operate, more of the waste is expelled from the blood, and the pathological products become too much for the absorbents to remove; they are soon organized and commence an independent existence. The diseased atoms in this parasitic mass become not only mechanically obstructing and depressing, but vitally also, by their morbid effect upon the life of the body. Under these great and overwhelming difficulties the mucous membranes of the bronchia become exuents through which these dead and dying atoms are expelled in the form of mucus, and the broken-down, dying, red corpuscles being added to the diseased white ones, a hemorrhage results. If we look at this state of things wisely and calmly, what are we to do? attempt to resist nature by arresting the hemorrhage with ergot, or leave this agent to the gynecologist? For it has no power to arrest a bronchial hemorrhage but rather to increase it; and if it were possible it were undesirable, for then would be retained in the circulation the morbific products which the organic life is endeavoring to expel.

The most rational, as well as the most successful, remedy is spirits of turpentine applied by frequent washings of the chest externally. This has the tendency to prevent or relieve pulmonary stasis: First, to remove the interpleural morbific exudates before organization has commenced; and, second, to revivify the sick corpuscles, both white and red.

The emergency having passed, we have to deal with organized products which, by continual contraction, are lessening the area for blood-aeration, and progressive emaciation results—consumption.

Spirits of turpentine is still a valuable agent, stimulating the absorbents and dissipating local congestion, and promoting the health of the blood-corpuscles in active circulation. But, above all things else, it is important to maintain and increase the area of blood-aeration. This is best done by simply breathing rightly, taking in as full respiration as is comfortable, and then holding the breath in for a short moment until the newly inspired air has mixed with the residual air, and has expanded under the rarefaction of the blood-heat. This must be continuous. It must be the all-time breathing; spasmodic or stated periods of correct breathing, of forced inspiration, will not succeed so well, for if the expansion is intermittent the pseudo-membrane will recontract at every intermission, and the fable of Sisyphus will be illustrated. For this reason, all mechanical methods of expanding the chest, although undoubtedly useful when not violent, are less beneficial than correct breathing which is continual. Change of locality, pine-woods, and mountain-climbing may all be beneficial.

Interpleural pathology has but a casual or accidental connection with tubercle. Tubercular inflammation, extending to the pleuræ, may cause plastic exudation within the pleuræ, and occasionally tubercle may come independently to the pleural membrane in general tuberculosis. And in this connection only will we refer to the bacillus tuberculosis, which has come to represent the disease. One thing is certain, that wherever a tubercular cavity in the lungs is found, there, in the cavity and in the tissues surrounding it, we expect to find in great abundance the bacillus. Wherever tubercular concretions or aggregations are found, there will the bacilli be also. But sometimes as well, but in far less proportion, where there are dead or dying atoms from mental anxiety or sorrow, scattered through the body, and, of course, in greatest abundance in the lungs, there, too, will be found bacilli. In regard to the question of contagion, or specific causation, of tubercle I shall not enter. But in regard to its connection with the dead and dying elements within the tissues of the body or in the circulation of the blood I have come to no conclusion except that the connection is casual, just as mould comes to decaying animal tissues by natural selection. And mould and the bacillus tuberculosis are suggestive of each other.

Movable Heart.—Dr. Rumpf reports five cases in which the heart, as was shown by the seat of the impulse and the area of dulness, changed its position in the thorax to an unusual degree in accordance with the position of the patient. In the most extreme case, the impulse in the erect posture was 61 to 62 ctm. from the left sternal border; in the right lateral position it was just to the left of the sternum; in the left lateral in mid-axilla; the distance between these two extremes was 13 to 14 ctm. The symptoms were inability to lie on either side without pain, oppression, and increased rapidity of the heart's action, with weakness, vertigo, and partial disablement as regards work. Four of the five patients had either just undergone treatment for corpulence or lost much flesh, a fact which strikes the author as very significant. He propounds the theory that the undue motility is dependent on the loss of fatty tissue from about the organ.—*Boston Medical and Surgical Journal*, September 6, 1888.

SOME OBSCURE AFFECTIONS OF THE RECTUM.[1]

By J. M. MATTHEWS, M.D.,

LOUISVILLE, KY.

What I shall have to say in this paper is in answer to a learned dissertation by Professor William Goodell, read before the American Medical Association (Obstetrical and Gynecological Section) at the meeting in Cincinnati, May 8, 1888. The title used by Dr. Goodell was "The Nervous Rectum," but the term most used in the article was hysteria or hysterical rectum. In other words, the position taken was that certain muscles become hysterical.

In explanation, he says: "The mind is sane, the organic body is sound, the individual, as a whole, is above reproach, and yet these muscles will behave as if they were bereft of reason." Further on, he says: "The muscles most liable to become *hysterical* are perhaps the circular ones, viz., the sphincters of the outlets and inlets, and while the insanity, so to speak, is more localized, the sufferings are perhaps greater."

The term employed here, "hysterical" rectum, is, in my opinion, misleading, and, while the importance of these affections cannot be overestimated, I am inclined to think that a caption such as heads this article, "Some Obscure Affections of the Rectum," is better for the elucidation of the subject than that employed by Professor Goodell—for the reason that it invites investigation. I dare say there is no physician here but has had some patient complain to him of some vague symptoms of rectal disease, when such diagnosis was not borne out by an examination. But you will permit me to say that it is too often the custom to dismiss these patients without an examination.

Webber defines hysteria to be "a diseased state of the *nervous* system, evidenced by an almost innumerable variety of symptoms." It is commonly classed as a *functional nervous disease* and has no recognized *pathological anatomy*. Dr. Goodell says: "In this form of hysteria there are usually present, in my experience, some one of the protean symptoms of general nerve-prostration, such as spine-aches and backaches, sore ovaries, uneasiness, wakefulness, and nervousness. But the chief suffering, or the most exacting symptom, is referred to some portion of the rectal tract, leading the physician to suppose he is dealing with some case of traumatic lesion. The act of defecation then gives great suffering, followed by a painful throbbing, which may last for hours. Patients thus affected so dread the suffering that they school themselves into habits of costiveness and often become victims to opium-eating." This is a perfect description of this class of patients; many of them would prefer death to living such a life, and we would not be stating the case too strongly to say that this condition will often end in actual insanity.

But is Dr. Goodell correct when he says that one of these "may lead the physician to suppose that he is dealing with some traumatic lesion?" To state it more definitely, *is not* the physician really dealing *with* a traumatic lesion? and can a cure be effected upon any other hypothesis? Certain it is that, if a lesion exists, the disease will not be cured until such lesion is eradicated; and, *per contra*, if no lesion exists, then the methods used for its eradication are *nil*. Let me cite a few cases: The following was given in a paper to the Kentucky State Society when I was discussing this subject. I have under observation a girl who has been treated for three years for chronic diarrhœa. The least excitement would cause her bowels to move. She had, on an average, six or eight evacuations a day. If a stranger came into the room, she had to go to stool; she could not go into society for this reason. For three years she had taken no nourishment save stale bread, milk, and weak tea. She had the protean symptoms of general nerve-prostration, viz., backache, wakefulness, nervousness, etc., together with a burning sensation at defecation, and an aching for hours afterward.

---

[1] Read before the Mississippi Valley Medical Association, St. Louis, September 26, 1888.

I gave this girl a careful examination, and found a sensitive spot in her rectum. Under chloroform, I divulsed the sphincter muscle and touched the spot with nitric acid. She made a rapid recovery. In a few days all looseness of the bowels had disappeared and she ate freely three times a day.

CASE II.—Dr. J. G. Carpenter, of Standford, thus relates a case in his own person. "I was the victim once of this spasmodic contraction of the sphincter ani muscle. Often, when riding on horseback, and feeling perfectly well, I would be seized with a sudden pain in the rectum, the sensation passing all over me as if I had been struck by lightning, causing me to drop the lines in agony of seemingly impending death. A few weeks would elapse before another attack; on very sudden change of the weather I was affected. Dilatation of the sphincter cured me."

CASE III.—William B——, aged forty-three, came to me with the following symptoms: At the approach of defecation he feels a severe pain up in the rectum, said by him to indicate the passage of the fecal mass over a sore place. During the act, a lancinating pain is experienced, and after the evacuation a dull, throbbing, aching sensation, which lasts for hours. A nervous exhaustion supervenes, which completely unfits the patient for any mental or physical labor. This condition has lasted about two years. The symptoms seemed so clearly to call for divulsion of the sphincter that, without a minute examination, it was done under chloroform, and the promise given that he would be relieved. Several weeks after he reported to my office, saying that he had not experienced any relief, and expressed the desire to die. I then carefully examined him and could find no lesion whatever. Recognizing the powerful effect of the reflexes in these cases, I advised that he go to a genito-urinary surgeon and be examined for stricture. This he did, and was told that he had both a meatic and deep urethral stricture. These were divided by the surgeon, and the man relieved of his rectal symptoms.

CASE IV.—Dr. H——, of Indiana, asked me at one of the medical societies to examine him, and gave me the following history: Several years ago, while prosecuting his professional duties, he was attacked by a terrific pain in the rectum. It was as if a sharp knife had been thrust through him. It would come on as paroxysms, with a few minutes only of intermission. He hastened to procure chloroform, and inhaled it at each approach of the paroxysm, until it gradually subsided and disappeared. He now carried a bottle of chloroform and regarded it as his best friend. Indeed, he said, "Nothing could induce me to part with it." He would likely go for weeks without an attack. Placing him in bed, I examined his rectum carefully with the index-finger; had no instrument with me. I gave it as my opinion that a lesion existed, perhaps only the exposure of a sensitive nerve, and that a free divulsion of the muscle would effect a cure. He afterward consulted Dr. Cook, of Indianapolis, who gave him a careful examination with the speculum, etc., and agreed to the diagnosis I had made. An operation was not done, but we met him months afterward and he reported that he had never had another attack, but still carried his chloroform.

CASE V.—A professional gentleman, sitting in his office with his feet elevated, felt a quick, sharp pain dart through the rectum near the verge of the anus. The pains came quick and sharp; he jumped to his feet and cried for help. A friend coming in caught him as he was in the act of fainting. The attack lasted about twenty minutes, and was quieted by opium. I directed that he be taken home and suppositories of opium and belladonna be administered for their full effect. The patient had three other attacks in as many days, after which nearly all intimations of rectal disease subsided after treatment, which consisted of a few washings of the rectum with hot water and the use of the suppositories. And so I might go on to cite cases of this kind, but will make these suffice to illustrate my subject.

CASES I., II., IV., and V. were evidently traumatic lesions, causing the exposure of a nerve, and Case III. was due to a traumatic stricture of the urethra, and the pain in the rectum was entirely reflex. Four of the cases were relieved by divulsion of the sphincter, and the fifth case did not succumb to the same treatment, for the reason that the disease was outside the rectum. Hence the statement. if these diseases are relieved by local measures, it proves the affection to be local, not hysterical, in the sense used by Dr. Goodell; primary and not secondary in their nature.

Secondly, if they be hysterical or secondary, local treatment would not relieve; but a constitutional course would be necessary. Says Dr. Goodell: "Sometimes the site of the rectal pain lies higher up than the sphincter muscle, and is irrespective of the act of defecation. It then is liable to show periodicity in its character, coming on at regular hours of the day; probably from the periodicity with which the accumulation of fæces in the lower bowel takes place." In these cases, at least, all idea of hysteria attacking the muscle must be dissipated; for the reason that the disease is above the muscle. This brings us to consider more minutely the pathological conditions found in obscure diseases of the rectum.

Believing hysteria to be a disease of the nervous system, as defined by Webber, having no recognized pathological condition, we have argued that it is impossible for a muscle to be attacked by such disease; that when evidences such as have been described are manifest, they are the result of disease at the seat of trouble or by reflex from continuity of structure, and that such evidences are usually the result of trauma. Without such recognition, the plan of treatment would be misleading, and no good results obtained.

Disease is often found above the sphincter muscle, which presents symptoms strongly resembling the so-called "hysterical" rectum. From what do these symptoms originate? Are they from some localized disorder of hysteria? or are they from a pathological condition? I maintain that disease exists at this local point and, as a result, we have pathological change; or, per consequence of disease in a contiguous part, we have disease made manifest by the reflexes. If either one of these propositions be true, then the idea of such diseases being hysterical in their nature cannot be sustained. Now I do not believe that such condition is an hysterical one; a better term would be neuralgic—though this would be far from correct. There are so many pathological conditions which exist in the rectum, either of which could present all the symptoms of the so-called hysterical rectum, that the necessity for an examination cannot be too strongly urged. For instance, the rectum, because of its peculiar office, of its deficiency of valves in the venous supply of blood, of its dependent position, etc., is quite liable to a congested condition and to an inflammatory state. Because of these two conditions, ulceration is often found in this portion of the gut. Foreign bodies frequently lodge in the pouch of the rectum, and by mechanical means produce trauma. The passage of hard fecal matter frequently results in a tear of the mucous membrane, and the making of a small anal fissure. Even the use of hard substances as a detergent will do the same. The enema-tube is known to be a cause of a wound at the verge of the anus. Small openings of internal fistulæ are a source of great irritation. As other pathological conditions which may be responsible for all the symptoms of an hysterical rectum could be cited: 1. Hemorrhoids; 2. Proctitis; 3. Injuries to or diseases of the uterus; 4. Stricture of the urethra; 5. Cystitis: 6. Enlarged prostate, etc.; indeed, any pathological state existing in or around the rectum. Until said state is returned to normal, none of the so-called hysterical symptoms will disappear. Constitutional treatment would be of no avail.

Besides the common diseases of the rectum, a few of which have been given here as causes of these vague symptoms, there are others of an obscure nature which are hard to detect. It is to these that I wish to call attention particularly. I can do no better than refer to Professor Goodell's paper: "There is yet another form of disease which, I think, may be classified under the general head of nervous rectum, although its pathology is by no means yet determined. I refer to pellicular colitis, or pseudo-membranous enteritis, as it is usually termed, in which mucous casts of the lower bowel are discharged, with much tenesmus and abdominal pain, either by themselves or in the regular evacuations." Such cases as these are frequently met with in my practice, and I cannot agree that the disease is a "sheer neurosis." I have seen the affection in patients not given at all to hypochondriasis, and relief has been obtained by remedies outside of those that affect the nervous system. I believe that in all these cases a disease exists, the result of pathological change: as the name colitis or enteritis implies, of inflammatory action. I have never yet succeeded in curing such a case, outside of direct or local medication.

Etiology.—The rational treatment of all diseases necessarily depends upon a correct diagnosis. How difficult this sometimes is all practitioners of medicine are cognizant. Disease, in the abstract, implies a morbid change: a pathological as a natural condition. I have headed this article "Obscure Affections of the Rectum," a term which in itself implies a doubt. Therefore it has been the object of the paper to demonstrate, by clinical facts, a basis of argument to sustain the position taken; viz., that these affections have their local origin in the rectum, and that all nervous manifestations are simply secondary to the same. If this premise be admitted, then the line of treatment is plain. Relieve the cause (local), and the manifestation (general) will disappear. If this premise is wrong and these troubles are "neurotic," *i.e.*, caused by a "disordered condition" of the nervous system, then the term, as used by Dr. Goodell, "nervous or hysterical rectum," is a correct one, and the line of treatment would be to correct the general condition and the local would disappear. I do admit that the effect of a "sheer neurosis" is sometimes remarkable and difficult to explain; but I am satisfied, after observations extending over a score of years, that these peculiar cases are not due to such conditions. For convenience of elucidation, I will give the following as the causes of these obscure affections of the rectum, which have such symptoms as have been narrated in this paper: 1. Hysteria (?) neurosis; 2. The reflexes; 3. A lesion, or pathological change, at seat of trouble.

Of all vague terms used by physicians, this one, hysteria, is the vaguest. Having reference, as the derivative of the word implies, to the womb, the profession has been in the habit of characterizing many affections of the female which they could not understand as hysterical. But so many symptoms analogous to them are presented in the male that we frequently see articles descriptive of them, and the same term used. I do not deny but that the nervous system is responsible for many strange freaks; but I do assert that much that is attributed to it has origin in a local way, where a pathological condition exists. In such a case all the treatment that could be given for the nervous system would avail nothing until the local disorder was relieved. On the other hand, it must be admitted that if the local condition was the cause, it should receive the first attention. Hence I am inclined to the opinion that in this condition of so-called "nervous rectum" a careful and minute examination of the parts should be given. This, I am sure, is very seldom done. If it be done, I assert that it would be the rarest of happenings to find a "nervous rectum" *per se*. Therefore I will be excused from considering hysteria as a cause of rectal trouble.

2. *The reflexes.*—No one doubts the part played by the nerves in reflex action, as a cause of disease and often of a mistaken diagnosis. It has been but a few years since Dr. L. A. Sayre startled the profession by his theory of adhered prepuce causing the spasms of infancy; vomiting as the result of a gravid uterus, epilepsy from strabismus, or a spasm from dentition are every-day examples of the force of the reflexes.

At the meeting of the International Medical Congress at Washington I had the honor of reading a paper entitled, "The Anatomy of the Rectum in Relation to the Reflexes." I cited cases to demonstrate that many diseases (?) of the bladder, uterus, ovaries, prostate, urethra, the cord, etc., were but manifestations of disease in the rectum through the reflexes; and, *vice versa*, it could be shown that many of the so-called rectal troubles could be traced to the same system of nerves. Therefore I conclude that many of the *obscure* affections of the rectum have their origin in contiguous parts. In many instances I have known a stricture of the urethra, an enlarged prostate, an irritable bladder, a congested ovary, an inflammation in the sigmoid flexure, to cause a most uncomfortable feeling, and sometimes intense pain, in the rectum. Therefore it is absolutely necessary in all of these obscure troubles to investigate all these parts. It is a well-recognized fact that all such troubles give rise to great nervous disturbances, but it would be folly to treat them without first curing the pathological condition.

3. *Lesions or pathological conditions in the rectum.*—This is, in my opinion, by all odds the most frequent cause of these obscure rectal troubles. Indeed, I am so fully persuaded of it that I will not prescribe for any patient who presents such symptoms as have been described without first subjecting the rectum and sigmoid flexure to a rigid examination. Since adopting this plan I can say it is the rarest exception that I fail to find the cause. Examination—what I mean by an examination—is not a casual survey of the parts, nor a half-way manipulation with instruments, but a careful inspection of the whole rectum, so described. I first direct the patient to take an aperient, after which the rectum is to be thoroughly washed out with a large enema of hot water. The patient is then put upon a hard table, and, with proper sunlight or, as some prefer, artificial light, a careful inspection made first of the anus. Sometimes a spicula of bone or other foreign substance may be detected in the verge, which, if removed, may stop all the trouble. An inspection is then made of the rectum proper To do this properly it is best to give an anæsthetic. A set of long gutta-percha speculums should be convenient and the size necessary selected. A Wales bougie should be fitted to or on the speculum, and, being well anointed, it should be gradually pushed in. When the edge of the speculum has passed well through the sphincter, the bougie should be withdrawn. Then by the aid of a good light the mucous membrane of the gut can be seen for six or seven inches. A careful search should now be begun for the trouble. Generally the eye is able to detect it, but I am in the habit of passing a long probe up the gut, and, by feeling around as the instrument descends, it will frequently touch the sensitive spot, and the patient notifies you of the fact. Other pathological conditions, such as congestions, inflammations, ulcerations, etc., can be detected by ocular inspection.

Treatment.—Under the head of treatment I am to take it for granted that a pathological condition is found in the rectum; I shall only refer to those that would likely cause symptoms simulating the nervous rectum (?). They are: 1. Fissures; 2. Ulcers; 3. Congestions; 4. Proctitis; 5. Internal fistulæ.

I shall not consider the treatment of the graver forms of rectal diseases such as result from syphilis or malignancy, although in their incipiency they are often attended with symptoms very like the more simple affections herein named.

Fissures of the anus may escape notice even after diligent scrutiny. Therefore I have urged a very careful search for any abrasion. If any lesion or pathological change is found which is embraced by the sphincter, the remedy *par excellence* is *divulsion of the muscle.* It may be argued that this would only temporarily relieve—that the pain would reappear after the fibres of the sphincter had regained themselves. In my experience this is not true. The rest given the muscle is quite sufficient to allow the healing of the fissure, etc. The manner of divulsion is an item. I neither break nor tear, nor use that violent force recommended by some. In lieu of all this I practise a rapid divulsion by means of a Cook's speculum, simply opening it to its fullest extent.

In Classification 2 I use the expression *ulcers*, in preference to ulcerations, the latter indicating a more extensive condition than is found in these simple cases. I refer more especially to the small ulcers that are often found along the course of the gut, and which require a very simple procedure for their cure. A probe with cotton on the end dipped in *pure* carbolic acid, applied through a speculum to the ulcer or ulcers, is generally sufficient to establish a healthy action and insure a cure.

3. *Congestions.*—The rectum is very liable to a congested state, because of its portal circulation; when congested, of course, many of the symptoms of reflex, etc., are present. A careful looking after the liver is essential; so it is my custom to first unload it with a cholagogue cathartic, after which a free administration of some aperient mineral water is recommended. The rectum should be washed daily by injections of very *hot* water. This course is generally sufficient. If any of the astringents are needed they may be added to the wash, but I much prefer the use of boracic acid—a teaspoonful to the pint of hot water.

4. *Proctitis.*—That the rectum can be inflamed seems to have escaped the minds of many. Because of its peculiar office, its abundant blood-supply, its want of valves in a portion of its venous supply, the erect position of the body, etc., it is very liable to become inflamed. When such condition exists, usually the only symptoms manifest are those of reflex. It is no wonder a patient is doctored for all manner of diseases which he has not. Pains in the back, legs, belly, ovaries, general lassitude, mania, nerve-prostration, headaches, bladder involvement, loss of appetite, melancholia, etc., are prominent symptoms of this trouble. It is no wonder that this trouble is frequently called *hysteria.* When these vague symptoms exist, I beg that the rectum be inspected. I know of no class of troubles that so affect the mind, even to a contemplation of suicide. If upon examining the rectum I find it inflamed, the following course is pursued: Free aperients, hot-water injections, a non-stimulating diet, perfect rest of the body, and the use of one of the following prescriptions as injection, to be used once daily:

℞. Sub-nit. bismuth .... ʒ j.
Iodoform .... gr. x.
Sweet-almond oil .... ℥ j.
M. S.—Inject.

℞. Fluid hydrastis .... ʒ j.
Aquæ .... ℥ j.
M. S.—Inject.

℞. Listerine,
Aquæ .... āā ℥ j.
M. S.—Inject.

In obstinate cases it is best to put the patient upon a fluid diet. The best article that I have ever used is bovinine, known as Buske's fluid food. In conclusion, permit me to say that I regard these obscure troubles of the rectum as worthy of your careful consideration. Many lives have been wrecked from the fact that patients so afflicted are neglected by the physician, and they fall into the hands of charlatans and quacks. Too much stress has been given in these cases to the nervous symptoms that present, and not to the local cause of the trouble. I cannot agree with Dr. Goodell when he says: "The treatment of a nervous rectum depends largely upon the general condition of the patient. If she have nerve-prostration, as she usually will, failure will attend every effort to cure the rectal disorder, unless the former is successfully treated. The very best general treatment for this condition of the nervous system is that devised by Weir Mitchell, which I have described in detail in the last edition of my 'Lessons in Gynæcology.' It consists of prolonged rest in bed, of seclusion from friends, of nutrition, of massage, and of electricity." I believe such a course, pursued with such cases, would be highly detrimental, and I cannot be too emphatic in saying, attend to the local cause and the nervous symptoms will take care of themselves.

TOXICOLOGICAL EFFECTS OF BORACIC ACID.[1]

By GEO. T. WELCH, M.D.,
KEYPORT, N. J.

BORACIC ACID has become generally known and esteemed in recent years for its antiseptic and germicidal powers, and its application has been extended in various directions to the treatment of diseases, especially those of a suppurative or catarrhal nature, and the drug not limited as to its quantity, under the impression of its harmlessness. I have myself used it in otitis, cystitis, and other chronic inflammations, with decided benefit, and from internal and external use in various affections, I gradually became accustomed to the opinion that it might be used in even large quantities without detriment, if not always with success. But even water and the atmosphere have their limits when viewed therapeutically in their effects on the human system, and I have found that boracic acid, under certain conditions, is not without its poisonous effect, and have reason to doubt the accuracy of the recent assertion of Gaucher, that "the fatal dose of this drug is two and a half ounces continued for at least ten days."

I have, since August of 1887, treated five cases of chronic leucorrhœa by packing the upper third of the vagina with boracic acid, once or twice a week, tamponing the lower canal, and permitting the mass to remain until liquefaction occurred, on the second or third day, when the tampon was withdrawn, and a moderately hot douche was used to cleanse the membrane. The curative effect was marked—far more so than when any other means were used. The treatment is not original, though I am not aware of the name of the first operator; nor is it essential, as the same processes in these minor matters doubtless occur to many minds about the same time; but I do not believe that anyone resorting to this means has recorded the same startling experience, in the end, that I have had.

My first case, Mrs. J. A. R——, was put upon this treatment in September of last year, after I had exhausted other means, and her patience as well as my own. She had become the despair of local physicians, and had been under treatment by a noted gynæcologist in New York, for some weeks, before she came under my care. Her leucorrhœa was, perhaps, the most excessive I had ever known of, being of a profuse, acrid character, demanding the application of several napkins daily, and causing an intolerable pruritus of the vulva. A chronic cervical endometritis from which she had suffered, had been right skilfully treated by my predecessor without relieving the leucorrhœa, but he had relieved himself by sending her back to the country.

The upper part of the vagina was highly vascular, deeper in color, and copiously exuding its secretion, to the extent of making it very difficult to dry it sufficiently for the application of the boracic acid. But having had the patient already under treatment for five weeks, with douches, astringents, suppositories, tonics, paintings of the membrane with solutions of carbolic acid and of nitrate of silver, tamponing, with various harsh drugs in solution saturating the cotton, etc., I was resolved to give the boracic acid an extended trial. I found it necessary to astringe the mucous membrane with nitrate of iron before it could be dried sufficiently to begin the experiment. The treatment was given on September 4th, 11th, 18th, and 25th, and on October 9th, 16th, and 23d, and November 13th. Finely pulverized boracic acid was used, and it was well packed and held in position by a tampon of dry absorbent cotton. The patient withdrew this on the third day and used a hot douche afterward; on the seventh day the process was repeated. From the very first application the troublesome disease began to abate, and November 13th the last operation was given—the relief being complete before this time for about fifteen days, when a slight moisture alarmed the patient, and caused her to send for me again.

---

[1] Read before the Monmouth County Medical Society, at Freehold, N. J., October 8, 1888.

I heard nothing further from the case until the 23d, when I received a telegram from her husband asking me to call. The family lived in a village about seven miles from Keyport. I was astonished at finding my patient bolstered in an easy chair, her hands, face, and feet having a charred appearance, as if dipped into some solution of caustic alkali; but her tongue was supple and voluble, and she was fierce in her denunciation of the treatment she had last received, alleging that all her trouble arose from that. As nearly as I could gather, it appeared that on the second day after the treatment there was some feeling of formication in the hands and feet, and later on in the face; the patient became low-spirited, and complained of great depression of the nervous system. There was an acrid escape of liquid from the vagina toward the second night, and the tampon was withdrawn and the douche used. As the days wore on the burning of the skin increased, but particularly that of the face, hands, and feet; the skin swelled, became charred, and all motion was painful. The leucorrhœa returned, was copious, and the eczema of the vulva was intolerable. Loath to believe that the boracic acid had anything to do with her condition, I cross-examined the patient closely and got an account of all the details of her life for the two days most in question, but could not learn of anything suspicious in food, drink, or toilet.

She had not sent for me before because of the hopelessness that had possessed her mind, but had at last yielded to the importunity of her husband. The skin of the worst affected parts subsequently exfoliated and the leucorrhœa ceased abruptly without further treatment. I examined the vagina about December 1st, and found it in a normal condition. I remained in a perplexed state of mind in regard to the matter until August 15th, of this year, when similar phenomena presented themselves in another case similarly treated.

This lady, Mrs. F——, was progressing very favorably indeed, when on August 15th she received treatment with the boracic acid the seventh time. Called to her hastily on the morning of the 17th, I found her in a state of collapse, the pulse barely perceptible, the eyes sunken, the face dusky, and the voice weak and whispering. She was in a low state of mind, had been weeping, and was full of foreboding. She complained of great pain in the vagina and of the corrosive discharge from that part. The hot douche had been used without benefit. I attempted to make a digital examination, but was forced to desist because of the pain it occasioned. I syringed the vagina with a large quantity of warm water, and upon examining found that the mucous membrane was corroded, and that a large ball of the acid, too hard to be broken up with the finger, was lying in the fornix. This I removed, as I did two smaller pieces, and by continuing the douche the vagina was finally cleansed. Oiled cotton was then introduced, and the excoriations treated. The temperature was $97\frac{6}{10}^{\circ}$ F., and the pulse 60, the heart beating feebly, the patient sighing and weeping by turns. Stimulants were used freely with decided benefit—brandy, ammonia, valerian—but it was not until the seventh day afterward that all the symptoms subsided; the patient being at times cold, and hysterical, and especially prone to melancholy. The urine was scanty during this week, and of course voided with pain. At the end of this time my attention was called to an exfoliation of the skin, which came away in branny scales.

I attempted on two occasions to examine the condition of the vagina with a Sims speculum, but had to desist on account of the pain caused, and the menses appearing, it was not until September 1st that I could satisfy myself on this point. The mucous membrane had been newly renewed, was dusky in appearance, and the os uteri was in a vivid state of inflammation.

At the time this accident occurred I was treating my fifth case of leucorrhœa, in the person of Mrs. J——, with the boracic acid; three cases had been cured, without any return, after several months, of the disease, and the present case had been progressing so well that it was with great regret that I felt obliged to discontinue the use of this drug. Other means failing to alleviate the chronic catarrh, I came to the conclusion that I would use smaller amounts of the acid, and that without packing it firmly as heretofore I would order the tampon withdrawn the following morning and the douche used. Accordingly, I procured a new supply of the acid from another chemist, and made trial with it on September 6th. Shakespeare says that

> "Truth can never be confirmed enough,
> Though doubts should ever sleep."

But I must confess that I am no longer curious in substantiating the toxicological effect of boracic acid, for twelve hours after the operation I was hastily summoned to my patient, whom I found with skin singularly cool, pulse feeble, respiration sighing, eyes sunken and dull, voice whispering, and mind unclouded but despondent. I gave stimulants freely, and douched the vagina thoroughly after removing the tampon. There was no corrosion of the membrane here, and the patient at the end of a few hours recovered her normal condition.

I should remark here upon the great coolness of the vagina when first examined, in both these cases. Where I have used ice in post-partum hemorrhages I have not noticed greater coldness in the parts than I have experienced here.

The amounts used varied from one to two ounces of the boracic acid, at each operation. In the first case the average must have been two ounces. When liquefaction began to occur, the escape of the fluid was prevented by the tampon of absorbent cotton, until this was saturated to the point of leakage, which was usually in about forty-eight hours. The great number of papillæ found in the mucous membrane of the vagina gives a large absorbent surface, which must be very actively engaged, under the circumstances above detailed, and argues a reason why the acid should more profoundly impress the system when lodged here for days, without external escape. Used as a boroglyceride upon a tampon, the affinity of the glycerine for water would draw upon the resources of the glands, and speedily produce a liquid discharge which would eliminate the acid. But I suspect that large quantities given by the stomach could not escape without some mischief, especially if there was any diseased surface along the course of the intestines.

The symptoms of poisoning by boracic acid resemble those of the caustic and carbonated alkalies. As found in nature boracic acid exists in volcanic regions, and is notably obtained from the lagoons in Tuscany, by building basins over the jets of vapor and boiling water which issue with violence from fissures in the earth; the basins being flooded with water from the mountain springs, the boracic acid is absorbed as it ascends in the stream, and being drawn off into basins at lower levels, is transferred to shallow tanks for purification. (Bowring.) The annual production is about three million pounds, and of this crude boracic acid one hundred and seventy-eight thousand seven hundred and ninety-eight pounds were imported to the United States in 1878. Whether it thus passes, to any extent, to the pharmaceutist, I am not able to say, though it is the general impression that the drug, as used in medicine, is first made into borax, and is again obtained from this in hot solution by adding hydrochloric acid, when it crystallizes in white translucent scales. It is soluble in thirty parts of cold water and in three of hot, and is soluble in alcohol, where it burns with a green flame, constituting a test of the presence of boron. Its solution exhibits an acid reaction with litmus paper, yet it turns turmeric paper brown, as do the alkalies. If heated for some time at eighty degrees, it loses the elements of a molecule of water, and is converted into metaboric acid; and heated for eight days to about one hundred degrees, four molecules unite, with loss of five molecules of water. (Witthaus.)

Boron is a most singular element, closely allied to carbon, and when isolated from boracic acid it resembles the diamond in lustre, hardness, and refractive power, and if larger crystals can be prepared it will take rank as one of the most valuable gems. In combination, as borax, it is fatal to the lower animal life; as boron fluoride, it carbonizes organic matter, as does sulphuric acid, and as boracic acid, I think I have shown it is not without its dangers when used in large quantities in the human system.

DEAF-MUTISM: ITS PATHOLOGY, CAUSES, AND TREATMENT.

By B. ENGELSMAN, M.D.,

NEW YORK.

Deaf-mutism implies muteness caused by deafness only. Muteness due to an organic defect of the vocal organs is not included in this class. Such cases are rare, and only one has come under my observation. It is an established fact that the mental faculties will act, if only stimulated by one of the intellectual senses. The senses convey the impressions made on them by our environment to the brain, and the latter converts them into ideas. Full possession of the senses promotes the development of the mental faculties; any defect of the former must necessarily leave a lack in the development of the mind. All observers concede that the loss of one or more of the intellectual senses will cause greater vividness of the others, owing to their extra exertion and education. The senses which take the place of hearing in deaf-mutes are sight, touch, and general sensation. By means of these senses they can be educated to converse in spoken language, and to enjoy dancing to music. I attended, last winter, a masquerade ball of deaf-mutes, where I had the pleasure to notice their joy in keeping time to the rhythm of the orchestra. Surrounding society exerts the same influence on a deaf-mute child as on a hearing one. A child brought up in a refined family will acquire refined habits, and *vice versa*. There is, of course, a difference in the intelligence of deaf-mutes, as in those possessed of hearing, for intelligence depends on the quality and quantity of the brain texture.

In examining the subject of deaf-mutism, we may divide deafness into two classes, viz.: congenital and acquired. Statistics differ with regard to the predominance of one class over the other, but we will be safe in assuming that over fifty per cent. are acquired. In regard to the ages at which deafness is most likely to occur, the *American Annals for the Deaf and Dumb*, of July, 1873, show that in 1,256 cases of acquired deafness there occurred under one year of age, 296 cases; between 1 and 2 years, 276 cases; between 2 and 3 years, 191 cases; between 3 and 4 years, 102 cases; between 4 and 5 years, 88 cases; and 5 years and upward, 207 cases. The census of the United States of 1880 shows that there are 18.567 male and 15,311 female deaf-mutes. The predominance of the males may be due to the fact that more males than females survive the diseases occurring in childhood. It is often difficult to determine whether a child is a congenital mute or has acquired deafness in early childhood. The following rule in the school-room will lead to a correct diagnosis: Congenital mutes acquire the mechanism of articulation with more difficulty than those who have acquired deafness, at whatever age this latter may have happened; the speech of both is monotonous, but that of the former is harsher, and attended, at the beginning, with contortions of the face. The external appearance of the deaf-mutes does not present anything noteworthy, except that many drag and shuffle the feet in walking, which is due to two reasons: 1, To the deafness, which renders them unable to recognize the disagreeable effect; and, 2, to the want of education. A continuation of this habit into adult life generally denotes a feeble mind. Their sense of feeling is very acute; in the school-room it is only necessary to clap the hands or stamp slightly with the foot to attract their attention when their backs are turned.

Pathology.—Congenital deaf-mutism may, in most cases, be ascribed to certain irregularities of the auditory apparatus. They may be external or internal. The external ear may be partly or entirely absent; the meatus externus may be narrowed or completely closed. In regard to the internal abnormalities, the autopsies of deaf-mutes furnish the most varying results. In many cases in which deafness resulted from nervous or other diseases no organic defect was found, while in others, again, various deformities were discovered. A few of the numerous post-mortems made by Hyrtl gave the following results (*Schmidt's Jahrb.*, 1838):

Case I. presented an example of ectopia cordis, four inches long and two inches wide, covered with periosteum, and with abnormal distributions of several arteries. The external ear, with the exception of the small muscles of the pinna, normal; the membrana tympani thickened and dried parchment-like; the malleus and incus atrophied; on the former was missing the processus brevis, and on the latter the os orbiculare; the laxator tympani was wanting also, and the tensor tympani was so indistinct that it might have been taken for a condensed cellular tissue; the cavity of the tympanum was nearly dry. To this extent both ears presented the same appearances, but the labyrinths presented dissimilarities. On the right side the fenestra ovale was adherent to the foot of the stapes, both crura were wanting, and instead of them there extended from the centre to the base of the stapes a single small pedicle, bent outward and downward, and at its point was missing the eminentia pyramidalis, with the stapedius muscle. The neurolemma of the auditory nerve was thickened, the nervous tissue reddish and smeary, the ends of the nerves vestibuli and cochleæ liquiefied into a brownish disorganized jelly. On the left side the fenestra ovale was closed by the stapes, which was very much atrophied, and its arms thinner than a hair; the eminentia pyramidalis, the rostrum cochleæ, and the external canalis semicircularis were wanting, although the pyramid in the outer pavilion, and the upper canalis semicircularis were completely developed. The nerves were similar to those on the right side.

Case II.—A girl, five years old, died of chronic hydrocephalus. On examination found the right temporal bone unusually developed, the squamous portion three times as thick as the other cranial bones; the mastoid process and cells of unusual firmness. The two tables of the temporal bone were nearly separated to the circumference, forming a cavity communicating with the cavity of the tympanum, and inclosing the head of the malleus and the body of the incus. The carotid canal was very narrow, hardly admitting a thin probe. The membrana tympani was split, as if a piece had been cut out. The fenestra ovale was almost obliterated. Of the semicircular canals only two were present.

CASE III.—At the autopsy of an adult deaf-mute he found the membrana tympani of the size proper to a seven-months' embryo, but very much thickened. The head of the malleus had an epiphysis with a broad base and pointed extremity directed forward to the Glaserian fissure. The base of the stapes was not larger than the os orbiculare and lay movable in the narrowed fenestra ovale; it was only connected with one of the processes, the other process of the stapes being free in the cavity of the tympanum. The cochlea had only two turns of the spiral, the remainder being agglutinated together; into this projected half of the atrophied malleolus. The lamina spiralis was entirely wanting, the semicircular canals were smaller and narrower. The bones around the labyrinth were harder and denser. The left ear had no stapes, and the fenestra ovale was closed by the growth of a bone which appeared to be the base of the missing stapes.

From the above post-mortems the conclusion may be drawn that the organic defects are not always symmetrical in both ears, and that the stapes is most frequently the seat of deviations from the normal. Congenital deformities may be due to intrinsic defects in the ovum, to arrested or obstructed development from various extrinsic causes, and in some instances they arise from the disease to which the fœtus is liable.

Predisposing or hereditary causes.—There is no donbt that the scrofulous diathesis is one of the predisposing causes of deafness. This condition produces its effect by exciting inflammation in the exterior and middle ear, and, when once started is liable to become chronic, and often causes perforation of the membrana tympani and discharge of the ossicle. With reference to heredity, the following cases came under my observation:

K——, of this city, became gradually deaf. Has four sons and a daughter; two of the sons are congenital mutes; one lost his hearing at the age of four years, and the girl is a cripple.

Mrs. R——, of this city, became partially deaf; she is also a cousin of her husband; one of her girls is a deaf-mute.

B——, of this city, lost his hearing at the age of four years, after scarlet fever; one of his sons lost his hearing at the age of five years from the same disease.

S——, of this city; partially deaf and afflicted with curvature of the spine; his grandchild is a congenital mute.

Marriages between near relations is another cause for congenital deaf-mutism. The *modus operandi* of this agency may be readily understood. Close intermarriages may transmit and intensify any defect which may be peculiar to the stock, while marriages of non-relatives leads to antagonism, and consequently diminution of any defect which may be peculiar to either of the parents.

The following statistics of the Allgemeine Oester. Isr. Jaubst Institute of Vienna confirms, at least partially, the above statement:

School years.	Number of pupils admitted.	Born of related parents.
1860–1861	9	2
1861–1862	10	2
1862–1863	16	4
1863–1864	15	3
1864–1865	11	4
1865–1866	10	2
1866–1867	12	2
1867–1868	13	3
1868–1869	23	5
1869–1870	14	3

This table shows that twenty-three per cent. of the whole number of pupils admitted were born of related parents. The relationships were as follows: The fathers of fifteen of these pupils were cousins of their wives; the mothers of fourteen pupils were nieces of their husbands, and the grandfathers of two pupils were cousins. Finally, I come to the consideration of accidental deaf-mutism.

The manner in which the inflammation extends to that part will be easily understood by calling to mind that the lining of the tympanum is a continuation of that of the fauces, and the affection of the throat soon finds its way through the Eustachian duct and involves the investing mucous membrane of the tympani. Other causes are inflammation of the external and internal canal—usually occurring in scrofulous children, of which I have treated before—acute otitis, otorrhœa, or the accumulation of wax in the meatus, etc.

Treatment.—If we read the literature of the subject we shall soon discover that manifold remedies have been employed for the cure of deaf-mutism. As in so many other medical and surgical diseases, empirical remedies came into fashion and were used indiscriminately in all cases, the etiology of the affection being entirely left out of view. If, perchance, one case was benefited in the slightest degree by a certain measure, the virtue of this remedy was exaggerated by the inventor, and henceforth it was used by most physicians connected with asylums for deaf-mutes. The French literature especially is rich in this phase of the subject. One instance only will suffice to illustrate the *modus operandi* of the fact just stated. At one time perforation of the membrana tympani came into vogue. Itard performed the operation on a deaf-mute. After the operation he employed injections of tepid water, which in the first few days caused the patient severe pains, and on the fifth day the injection escaped through the Eustachian tube into the mouth. This was followed by cephalalgia, dizziness, and vertigo, which were the symptoms of the sensibility of the organs of hearing, and by and by, Itard says, "the patient began to hear and to speak. But, unfortunately, the patient died soon after the operation, from tuberculosis." Itard performed the operation on thirteen other deaf-mutes, but without favorable results.

Dr. DeLau, jr., says, in his book, "Mal de l'Oreille," that he performed the same operation on two female patients, one sixteen and the other twenty-one years of age, and soon after the operation the patients began to hear and to speak a few words. He refers to three other cases in which the patients were benefited by the operation. The publication of these cases attracted the attention of physicians in different countries, especially in Belgium and Holland, so that the method was tried at the asylums on not less than eighty pupils, and, of course, without favorable results. At other times galvanism, magnetism, and other remedies were in vogue.

Deafness, as I have remarked, depends on different causes, and in cases in which a correct diagnosis can be made we may sometimes be able to remove the cause, as, for instance, in a case reported by Dr. Schleifer, of Neuhof (Ober. Oest.). The patient, a girl of nine years of age, who suffered a great deal from scrofula since infancy, began, at the age of seven years, to gradually lose her hearing, and at the age of nine years, when she came under observation, was completely deaf. The abdomen of the patient was enlarged, and, combined with other symptoms, Dr. Schleifer presumed the patient was suffering from worms, and accordingly ordered anthelmintic remedies. By a continuation of this treatment for six weeks eighty-seven pin-worms and over two hundred ascarides, combined with jelly-like mucus, were discharged, and at the end of six weeks the patient regained her hearing and speech. But in cases in which therapeutic remedies are of no avail, what measures shall be employed for the relief of these unfortunates? There are no other means at our command than to educate them. In infancy no difference can be appreciated in the mental characteristics of deaf-mutes and those having their full senses. The emotions of the deaf-mute are expressed in an exactly similar manner; when pleased, it smiles and moves its limbs lustily, and when displeased it weeps and turns away from mother and nurse. As the child begins to appreciate surrounding objects, it expresses its desires in the same manner as other children before they have acquired the power of speech; but as time passes it becomes apparent to the parents that their child cannot hear, and a change is noticeable. The necessity of communication produced spoken language. In deaf-mutes the same inexorable necessity produces a language by natural signs. The difference which must exist between these two products is obvious—the former can express abstract ideas and the latter only concrete; from this stage of development two systems of education are in vogue, the German and the French. The German method follows nature, inasmuch as it gives the child a living word in articulate sounds for each natural sign it has invented; as a consequence these signs are gradually dropped as the child becomes familiar with the word, and soon the child advances from the single words to simple sentences, and slowly passes from concrete to abstract ideas. The French method, on the contrary, develops, from the natural signs which the child has invented, an artificial sign language, which has no analogy in construction with spoken language, and compels the pupils to translate this highly artificial language into our language.

Without further comment I shall merely reproduce the judgment of the inventor of this system, the Abbé de l'Épée, contained in two letters addressed to his follower, the Abbé Seccard, "De Gerando," vol. i. p. 479. He says: "Do not expect that your pupils will ever be able to express their thoughts in writing, their language is not our language. Be satisfied if they correctly translate ours into theirs, as we ourselves may translate foreign tongues without being able to think or express ourselves therein, and that your pupils, like mine, can write dictated signs."

In the second letter he blames Seccard for attempting to make authors of his pupils, inasmuch as his system could only produce copyists; teach your pupils declensions, conjugations; teach them to construct parts of sentences after the model given by you; do not flatter yourself, however, that your pupils will ever express themselves in French; they will do this as it is possible for me to express myself in Italian, although I can translate the language tolerably well

The German method has the additional advantage that it causes greater physiological development of the respiratory organs by the practice of articulation. To produce a letter, certain movements of the organs of speech are required, these the deaf-mute acquires by imitation, and as a consequence learns to recognize them when produced by others, and in this way reads from the lips-mouth of others what is spoken. Some perfect themselves in lip-reading to a very astonishing degree. As a proof that those taught by articulation think in language, I may state that I have heard them frequently talk in their sleep. Any deaf-mute educated by the method of articulation can only think in this language, for he knows no other. He will use his mutism in his writing and will be a better scholar than when educated by signs. Articulation brings him nearer his hearing fellows, while the sign language widens the already existing inequality between him and his hearing fellows, and makes them a community by themselves.

CIRCUMCISED BY A MATERNAL IMPRESSION.—Dr. John G. Harvey, of Blue Mound, Ill., relates the following: "On August 11, 1884, I performed the operation of circumcision on a boy, three years of age, for the relief of a nervous trouble. On March 31, 1885, just seven months and twenty days later, his mother gave birth to a boy who was as perfectly circumcised as the child upon whom I had operated; even the scars from the sutures were reproduced in the exact number and location of those on the organ of the boy upon whom I had operated."

Progress of Medical Science.

RUPTURES OF THE BLADDER AND THEIR TREATMENT.—In connection with a successful case of suture of a laceration of the bladder, Dr. Blum gives some instructive statistics. The cases are naturally divided into intra-peritoneal and extra-peritoneal. Quoting the statistics of Bartels, out of 75 cases of the second class 46 were fatal, while of 94 cases of the first class 93 ended in death. When the rupture is joined with fracture of the pubic bone the prognosis is still worse—130 deaths in 139 cases. The seat of the lesion is variable, being in the intra-peritoneal cases almost always posterior, and in extra-peritoneal cases generally anterior. In general there is but a single laceration, and this seldom exceeds five centimetres in length, though rarely a double rupture has been seen. The principal symptoms are violent pain in the hypogastrium at the moment of the accident and great desire to urinate, without any result. Catheterism generally results in a few drops of bloody urine only, though in a few cases after several trials escape is afforded to a considerable quantity of urine, either clear or slightly tinged with blood. In these cases the catheter passes through the laceration and into the peritoneal cavity, or into the extra-peritoneal collection of urine. In extra-peritoneal rupture spontaneous recovery is possible, especially if there is an external wound, and if the patient is not carried off by urinary infiltration and inflammatory complications. In intra-peritoneal ruptures left to their own course death is the unvarying result, usually ensuing within twenty-four hours, and always within the first week. The diagnosis as to the seat of the laceration is often difficult, more especially if there is no external wound. If to the signs already mentioned there are joined pain all over the abdomen and marked tympanites, the chances are greatly in favor of intra-peritoneal rupture. If, on the other hand, there is no tympanites, but if there are marks of urinary infiltration of the abdominal wall, or if a fluctuating tumor above the prostate is made out by rectal touch, the rupture is probably extra-peritoneal. In the latter case perineal section and permanent catheterism are absolutely indicated, and have given good results. In intra-peritoneal rupture all the danger comes from communication between the bladder and the peritoneum, and the treatment is very different. Laparotomy is indicated, and should be done with as little delay as possible, to reveal the size and situation of the rupture, and it should be closed completely by the method of Lembert (the sero-muscular suture not involving the mucous membrane). The toilet of the peritoneum should be made with care. In twelve cases treated in this way there have been five successes, and Blum's makes one more. He was called in a case of this nature forty hours after the accident, and when the signs of commencing peritonitis were unequivocal. Nevertheless, the recovery of his patient supports the bold line of treatment which should be adopted, in which alone there is any hope of success.—*The New York Medical Journal*, October 6, 1888.

DISINFECTION OF SURGICAL INSTRUMENTS AND DRESSINGS.—Dr. Renard states that the disinfection of instruments by a five per cent. solution of carbolic acid is unreliable, the germs withstanding a soaking of from thirty to forty-five minutes. Bichloride is reliable, but has a chemical action on the instruments. Flaming, if thorough, is efficient. Boiling at 212° F. is efficacious, if long continued. Steam at 230° F. destroys all germs, if the substance be submitted to it for thirty minutes. Renard has a copper cylinder boiler that he fills about an eighth full of water; baskets containing instruments, and provided with feet that raise them from the surface of the water, are put in the cylinder, a lid containing a manometer and a safety-valve is screwed in place, and by means of an alcohol lamp the water is boiled; the air in the cylinder passes off by a stop-cock in the lid, which is then closed, and the pressure is increased until it represents a temperature of 230° F. Absolute disinfection is obtained in half an hour. Sponges are not subjected to this temperature, and instruments are never subjected to a temperature of more than 245° F. He draws the following conclusions: 1. Disinfection by steam compressed at 230° F., as applied in the apparatus above described, is certain and practical. 2. Instruments or dressings submitted to this treatment for fifteen or twenty minutes are absolutely disinfected. 3. The apparatus is very simple, not dangerous, and can be trusted to a nurse. 4. Neither dressings nor instruments are in any way altered by a prolonged treatment, if the temperature does not exceed 230° F.—*Boston Medical and Surgical Journal*, September 20, 1888

THE TOXICITY OF ALBUMINOUS URINE. In pursuing researches similar to those of Bouchard upon the toxicity of urine, MM. J. Teissier and G. Roque have communicated a paper to the Paris Academy of Sciences upon the character of albuminous urine in this respect. They point out that the determination of the toxicity of the urine is of great value in the prognosis of a case of albuminuria, but that the degree of this toxicity may vary at intervals, so that more than one estimation is needed. It does not matter whether there be much or little albumen in the urine if renal elimination be imperfect. They characterize albuminuria as a symptom of secondary importance in renal disease. The injection of albuminous urine into animals produces different effects from the injection of normal urine, and the most highly toxic specimens are those which contain most nitrogen; while in some the toxic effect is proportionate to the amount of albumen. The value of these laboratory researches is minimized by the fact that at present we do not know of any clinical indications of the degree of toxicity of the urine.—*The Lancet.*

TREATMENT OF UNUNITED FRACTURE OF THE NECK OF THE FEMUR.—Professor Loreta has successfully treated an ununited intracapsular fracture of the neck of the femur, by scraping the fractured surfaces and inserting a bundle of metallic sutures between them. On January 23d a robust man, aged thirty-six, was admitted into the Bologna clinic with the history of a fall on the left hip nineteen months previously, since which he had been quite unable to stand and had suffered from constant severe pain, shooting from the left hip joint into the gluteal region, the point of greatest intensity being over the course of the sciatic nerve. The limb was much wasted, but it was normal in position and scarcely at all shortened. Flexion and extension of the thigh on the pelvis were almost impossible, but the patient could occasionally execute very slight movements of rotation and abduction. In rotation he was sometimes conscious of faint crepitus in the trochanteric region. On February 15th Professor Loreta operated, with full antiseptic precautions. He made a long incision behind the great trochanter, so as to expose the capsule of the joint, when he noticed a depression between the intracapsular and extracapsular portions of the neck of the femur. On moving the limb it was found that there was a fracture without displacement in that situation. The capsule was then opened, the fibrous tissue between the fragments divided, and the fractured ends carefully freshened by scraping with a raspatory. As it would have been very difficult to wire the fragments, a bundle of from eight to twelve metallic sutures was introduced between them, and brought out at the lower angle of the external wound. The wound was carefully cleansed, a drainage-tube inserted, the edges brought together with deep and superficial interrupted sutures, and the whole covered with a sublimate dressing. A long outside splint was then applied. Five days after the operation the bundle of metallic sutures was removed, and the wound healed by first intention. In less than a month the pain had permanently ceased, and fifty-five days after the operation the patient left the hospital, being able not only to stand, but to walk with no further support than an attendant's hand.—*The British Medical Journal.*

WOUND OF INTERNAL MAMMARY ARTERY: HÆMATO-MEDIASTINUM.—A remarkable case of this kind recently came under the observation of Dr. Madelung) *The British Medical Journal*). On September 2d a man, aged thirty-nine, was stabbed with a knife in the head, thorax, and abdomen. But little hemorrhage was noticed; he walked one hundred paces, reaching his dwelling, where it was found that intestine had prolapsed through the abdominal wound. Twenty hours after the injury he was taken in a wagon to the Rostock Infirmary, after a journey of over an hour. The intestine was reduced, having been left alone till admission, and the abdominal wound sewn up. The thoracic wound was on the right side, parallel to the third rib, beginning close to the border of the sternum. It was four-fifths of an inch long, and no blood escaped from it at the time; it was drained and sutured. There were no signs of cardiac or pulmonary mischief. On the evening of September 13th, after doing well for many days, pain and dyspnœa troubled the patient, and hemorrhage occurred from the thoracic wound, which recurred on the evenings of the 14th and 15th, so that the patient became anæmic. On September 16th Dr. Madelung opened the wound. The right third costal cartilage was cut through close to the sternum. Arterial hemorrhage was observed above and below the cartilage, about an inch of which was resected. A cavity in the anterior mediastinum, "the size of a goose's egg," was exposed; it was full of clot. An inch of the fourth costal cartilage was resected; in so doing the operator opened the pericardium. Apparently that serous sac had been opened by the stab, and had speedily closed, the operation breaking down the adhesions which closed it. Much hemorrhage accompanied the opening of the hæmato-mediastinum, the blood gushing from the lowest part of the wound. Dr. Madelung therefore tied the internal mammary artery in the fifth intercostal space, in its continuity, when the hemorrhage ceased. The cavity was packed with iodoform gauze, and a tampon of the same material was placed over the wound in the pericardium. The patient recovered.

THE TREATMENT OF PULMONARY ABSCESS.—Drs. Spillman and Haushalter discuss the subject of abscess of the lung following acute pneumonia—a somewhat rare event. They reproduce abstracts of nine recorded cases where pneumotomy was had recourse to—in seven with success (*The Lancet*). All these cases were operated upon long after the pneumonia had subsided, in two after the lapse of two and five years respectively. Surgical intervention should, in their opinion, not be delayed so long, owing to the risks involved both locally and generally in leaving an abscess in this situation unrelieved. The diagnosis is therefore all-important, and is based upon the supervention of hectic after pneumonic defervescence, of purulent or gangrenous expectoration containing shreds of lung-tissue, fatty crystals, etc., and the physical signs of excavation. Recognizing the frequent insufficiency of these latter signs, they urge the use of exploratory puncture, which was adopted in most of the cases referred to. Pleuritic adhesions may have resulted from the previous pneumonia, but in some cases they are lacking, and may have to be artificially produced, either by resection of a rib and suture of the pleural layers, as suggested by Rüneberg, or by exciting pleurisy by means of the cautery as Cerenville did. Rüneberg, however, does not think the absence of such adhesion contra-indicates the operation. The authors record a case of their own where signs of abscess at the right base appeared on the fifteenth day of pneumonia, and where the diagnosis was confirmed by exploration. Glycerine and iodoform were injected into the abscess, but the patient died on the following day from collapse. The paper concludes as follows: "1. Before having recourse to operative intervention, one must be quite certain of the existence and site of the abscess by every method of diagnosis, and especially by exploratory puncture. 2. When an abscess is diagnosed in the course of pneumonia, intervention should, as a rule, not be entertained; but if the pneumonia is cured and the abscess persist, then intervention may bring about rapid recovery, or at least prevent serious accidents resulting from the opening of the abscess into neighboring organs or externally. 3. Before opening the abscess, it is useful to provoke pleural adhesions, if these do not exist. 4. To reach the abscess, the best procedure seems to be resection of rib and piercing the lung by the thermocautery. 5. The complete escape of septic fluids must be effected by drainage; antiseptic injections are to be avoided, and dry dressings to be preferred."

The Advantage of Borax and Boric Acid.—The Paris correspondent of the *Journal of the American Medical Association*, September 15, 1888, writes that Dr. Bedoin has pointed out the advantages of borax and boric acid. He states: 1. Borate of soda or borax, and particularly boric acid, possess incontestable antiseptic properties, the activity of which is not so small as is generally affirmed. Both are recommended for the preservation of alimentary substances, such as milk, butter, cheese, eggs, butcher's meat. But owing to its almost absolute insipidity, boric acid should, for this purpose, be preferred to borax, the savor of which is disagreeable; both are absolutely innocuous. 2. Interiorly the therapeutic employment of boric acid as an antiseptic has already given very encouraging results, which are of a nature to authorize its administration in the affections where, till now, carbolic acid was almost exclusively employed, for example, typhoid fever. 3. Exteriorly, the antiseptic properties of borax, and particularly of boric acid, justify the generalization of their employment in surgery, notably in the practice of dressings after the manner of Lister, also in certain affections of the urinary organs, of the eyes, ears, and of the skin.

Physiological Effects of Russian Baths.—Dr. Makovetski, of Professor Manassein's clinic in St. Petersburg, has published as a graduation thesis an elaborate investigation made by him on the effect of the so-called Russian bath on nitrogenous metabolism, and on the assimilation of fat and the nitrogenous principles of food. His researches were carried out on four student friends in a condition of perfect health. The baths were given daily for five days; perspiration in a hot chamber was induced, with the usual amount of shampooing, no steam being used. Accurate analyses of the urine, etc., were made for five days before the baths, for the five days during which they lasted, and for two days subsequently. It was found that the assimilation of the nitrogenous parts of the food was diminished, the nitrogenous metabolism being increased. The loss by the lungs and skin was markedly increased, but the urine was diminished, the uric acid, too, was diminished during the days when the baths were given. The baths have the effect of strengthening the muscular and nervous systems, and of increasing secretion where there is much muscular work, especially where the food is deficient in nitrogen, when there is a large amount of nervous and mental activity, and also when there is deficient action of the secretory organs in consequence of preceding hypersecretion, or morbid conditions such as chronic catarrh of the bronchi, stomach, intestines or genito-urinary tract, chronic hepatic, renal, or splenic affections. In these cases, together with the baths, fats and hydrocarbons are required in the food. As contra-indications, theory would lead us to include all conditions where the nitrogenous metabolism is diminished, and also those where artificially induced diminution of it appears to act prejudicially.—*The Lancet.*

Hot-Water Baths in Chronic Synovitis of the Knee.—The Italian correspondent of the *British Medical Journal* (September 15, 1888) says that Dr. G. Allexich, of Crema, has used hot baths with good results in six cases of chronic synovitis of the knee, in some of which the affection was of many months' standing, and had resisted all ordinary treatment. Dr. Allexich makes his patients keep the knee immersed in hot water for half an hour at a time. The joint is placed in the water in a flexed condition, and the patient stands upright, resting the weight of his body on the sound limb and supporting himself with his hands on the backs of two chairs. When taken out of the bath the knee is carefully dried and wrapped in cotton wool, the joint finally being carefully bandaged. For some days the patient should only go about on crutches. Dr. Allexich thinks that the virtue of various hot springs renowned for the cure of joint affections (such as Acqui, Abano, Viterbo, Ischia, etc.) consists not in their chemical composition, but in their temperature, and that equally good effects can be got at home by the simple means just described.

Australian Treatment of Typhoid Fever.—In compliance with the request of the Sydney Board of Health, Dr. W. Peirce, medical superintendent of the Coast Hospital, has reported upon the treatment of cases of typhoid fever, of which the rate of mortality during the first five months of the present year has been unusually low. Dr. Peirce, in his memorandum, states that, in cases received within the first ten days of the disease, calomel (three to five grains) is administered; and after that acetanilide, in five-grain doses, whenever the temperature exceeds a certain point (101° to 103° F.), up to six or eight times in the twenty-four hours. The effect of this is to cause a fall of temperature in about forty minutes, attaining its minimum in from two to four hours, with concomitant fall in the pulse and respiration rates, with decrease of arterial tension and profuse sweating. The tendency to delirium is diminished, and there is "a remarkable feeling of ease and repose, which appears partly to depend on the production of a certain amount of peripheral anæsthesia." When the effect of the drug passes off, the temperature often rises with great rapidity. He considers this treatment to have many advantages over cold bathing. He has given the drug continuously for several weeks, and has not found it contra-indicated, even when there were cardiac complications. It renders the course of the fever milder, but it may not lessen the duration of the disease. In all cases where it is freely given there is liability to occasional cyanosis of extremities and face, with irregular pulse. Alcohol was given very sparingly, and generally only in cases of failing heart. The author also maintains that the prolonged use of alcohol is very injurious.—*The Lancet*, September 15, 1888.

Lead Poisoning from Glazed Earthenware.—It is far from generally known that the use of glazed earthenware pans for preparing home-made bread, etc., is attended by the risk of lead poisoning due to the glaze becoming dissolved, and giving rise to more or less serious symptoms. In view of some recent cases of intoxication due to this cause at Alcester, it has been suggested that the fermenting process should be carried out in wooden vessels. Lead poisoning is a contingency against which the medical man requires to be on his guard. It occurs in the most unexpected places, and under circumstances which are very apt to escape his attention. The sources from which it has been known to be derived are varied in the extreme, and have often baffled the efforts to afford relief, until someone more far-seeing than the others has set to work to investigate the causes which underlie the perplexing ailments to which the ingestion of lead in any form is apt to give rise. There is scarcely an article of food, and still less of drink, which is not liable to contain the toxic agent, and nothing but constant vigilance can protect the practitioner from the results of an erroneous diagnosis.—*The Medical Press.*

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place

New York, November 3, 1888.

THE ELECTRICAL PROPERTIES OF THE HUMAN HEART.

THE idea that "electricity is life," and *vice versa*, is one which decidedly tinctures the minds of a large class of imperfectly educated people. There is, however, not the slightest reason to believe that vital force or nervous "discharges" have any closer identity with electricity than with heat, or magnetism, or light. The energy in a nerve impulse or muscular contraction is one of a distinct type, and only correlated with electricity, just as electricity is correlated with other manifestations of force.

There are, however, peculiar manifestations of electricity associated with the phenomena of the living organism. An electrical disturbance depressing in character accompanies the passage of a nerve-impulse, the secretion of a digestive juice, or the contraction of a muscle.

As a burning candle gives off at the same time heat and light, so the body, in manifesting vital phenomena, develops also electrical phenomena. These latter are very slight in amount, and can only be studied by instruments of great delicacy and precision; yet, with the aid of rude instruments, very curious and important observations have been made.

There are none more curious than those recently described by Dr. Augustus D. Waller, in an introductory lecture delivered before the St. Mary's Hospital medical school, on "The Electro-motive Properties of the Human Heart." Dr. Waller has observed what other physiologists had done, that with every beat of the heart in cold-blooded animals a wave of electrical disturbance passes from base to apex. He has lately tried to find whether the same phenomenon occurs in warm-blooded animals, and asserts that it does. Only, in the case of warm-blooded animals he thinks that the contraction begins at the apex and travels toward the base. If this be so, it will revolutionize some of our theory of cardiac pathology.

Dr. Waller has next tried to find whether the cardiac electrical phenomena occur in man. To do this it is only necessary to dip the two hands into two basins of water which are connected by an insulated wire with a delicate electrical indicator. With each heart beat a wave of positive electricity—to use conventional terms—starts from the apex and diffuses over the left and lower half of the body, while a wave of negative electricity diffuses to the right arm, head, and neck. More strictly, there is established with each heart-beat a difference in electrical potential over these areas, the degree of which is measured by the indicator. Dr. Waller succeeds in obtaining an electrical cardiogram of a certain definite character. A study of the variations in the electrical disturbance of the heart in various morbid conditions may furnish instructive data for the clinician and therapeutist.

FOOT-BALL PATHOLOGY.

WE are at the height of the foot-ball season, and the weekly record of casualties in various college towns and athletic associations is considerable. Such casualties are usually those of strains, bruises, wounds, with occasional severer injuries. It would hardly be thought that foot-ball could, like tennis and base-ball, produce a special form of trouble; yet, according to Dr. George Werry, in *The Lancet*, such is the case. The physician in question says that the most common foot-ball accident which he is called upon to treat is one known technically as "the poop." Whether such term has become adopted in this country or not, we cannot say; but certainly the accident occurs here.

The description of the injury given by Dr. Werry is this:

During the game a player receives a blow on the front and outside of the thigh; there is at once a feeling of utter helplessness, but he may recover so far as to be able to continue the play after a short rest, and feel little of it next day, except that he cannot run. The patient comes to consult the physician the day after the injury, with little pain. He limps in walking. On examination there may be effusion into the knee-joint, a soft and somewhat tender area over the quadriceps extensor femoris, and the patient cannot lift the limb when it is kept extended. Ecchymosis is not common. The amount of knee-joint effusion depends on the position of the injury with regard to the bursa behind the quadriceps tendon, and whether the man has tried to continue his sport, or walked much after the accident. The blow may be in the middle of the thigh, and cause an effusion into the joint; the patient may have forgotten the "poop," and come to complain of the swollen knee. The recovery of the damaged muscle is generally complete. It seems probable, therefore, that in the "poop" the muscle is more bruised than broken.

SPLANCHNOPTOSIS.

SOME time ago we published a description of an alleged new disease or morbid condition called enteroptosis, or falling of the bowels. M. Glenard, who is the originator of this term, and who first called attention to the condition, thought that it was not infrequent, and that it caused many of the nervous and dyspeptic phenomena of chronic invalids. This condition, referred to by Glenard, has been described by Beard as gastric neurasthenia, by Arndt as a nervous hypertrophy, by Leube as a primary or acquired gastric ectasia, by Bouchard as a primary enfeeblement of the gastro-enteric muscular system with relaxation of gastro-intestinal walls, enfeebled digestion, and absorption of leucomaines, ptomaines, etc.

M. Glenard's view that enteroptosis or ptosis of parts of the bowel or of the kidneys, or stomach, may cause many of the nervous phenomena of gastric neurasthenia has received attention from M. Féréol, who thinks the condition does exist, and that the fact is an important clinical one.

Dr. M. J. Cuilleret, of Lyons, has recently contributed some further evidence regarding this condition (*Gazette des Hôpitaux*, 1888, No. 109). M. Cuilleret reports the history of a case of enteroptosis with nephroptosis, diagnosticated as such by Glenard during life. Autopsy proved the accuracy of the diagnosis. Dislocation of the kidney is one of the frequently observed forms of "ptosis." Glenard has published statistics of one hundred and forty-eight cases observed at Vichy. This dislocation may cause no symptoms if slight, or it may cause nervous or gastro-intestinal symptoms. Prolapse of the ascending colon, with consequent stenosis of the transverse colon, is another frequent condition; and it is asserted that there may be gastroptosis without dilatation of the stomach.

Among about forty female and twelve male dyspeptic and nervous patients, Cuilleret found seven cases of enteroptosis, or, as he chooses to call it, "Glenard's Disease." The conclusions which he draws from his studies are:

1. Enteroptosis, either pure or accompanied with ptosis of other abdominal viscera, is a morbid entity sharply defined and very frequent.
2. This disease is characterized anatomically by a prolapse of the bend or knee of the ascending colon, and of the first part of the transverse portion. This is the fundamental organic lesion, constant and irremediable, of enteroptosis.
3. The affection described as movable kidney ought to be considered as in reality an affection of the digestive tube, for there can be no prolapse of the kidney without a prolapse of part of the colon or small intestines.
4. The subjective symptoms of especial significance in enteroptosis are: General weakness, insomnia, constipation, intolerance of certain foods. Tension and sensitiveness of the cæcum are the only objective signs at first Careful and deep palpation must however be made.

A history of traumatism, falls, repeated childbirths, and other things tending to weaken the abdominal walls must be sought for.

The treatment consists in bandages, laxatives, alkalies, a diet of meat and eggs, alkaline waters, and hydrotherapy.

THE TREATMENT OF URETHRAL STRICTURE BY ELECTROLYSIS A FAILURE.

Dr. E. L. Keyes, after a faithful trial of electrolysis in stricture, pronounces the method a failure. In a paper on this subject, published in the *New York Medical Journal* of October 6, 1888, he says that a wide-spread belief exists in the community, lay as well as medical, that material progress has been made of late years in the use of electricity as applied to the cure of urethral stricture. This belief includes the three presumptions:

1. That anyone, by following rules, may use the method successfully.
2. That electricity does no harm to the urethra.
3. That stricture cured by electricity is dissipated by absorption, and the urethra remains permanently open.

There is no foundation for these beliefs. Dr. Keyes had occasion to observe eight typical cases, in which the method, as advocated by Dr. Newman, was given a fair trial. In one of these cases, Dr. Newman himself applied the electricity. All the cases proved to be failures. Dr. Keyes concludes his article as follows:

"I may state that electrolysis with a very mild current—I prefer to put it at less than two milliampères and a half—does no harm; in fact, does nothing that I can appreciate, and does not interfere with the benefit to be derived from ordinary dilatation. I believe that a strong current is full of danger, both immediately from irritating effect and ultimately from cicatricial effect; and that employment of the negative pole does not prevent this.

My study of the subject and the experience it has brought me, digested with all the impartiality I possess, lead me to state that the allegation that electricity, however employed, is able to remove organic urethral stricture radically, lacks the requirement of demonstration. The confidence of its advocates that it will radically cure organic fibrous stricture is, in my opinion, due either to the combined credulity of the patient and imagination of the surgeon, or to some special but fortuitous act of Providence, upon the co-operation of which, in the case of his own patients, the general practitioner cannot with any confidence rely."

THE DIAGNOSTIC SIGNIFICANCE OF A RED GINGIVAL MARGIN IN PULMONARY TUBERCULOSIS.

The diagnosis of pulmonary phthisis in its early stages is often beset with so many difficulties that an acquaintance with even the most trivial signs is a matter of considerable importance. One of these minor symptoms, to which a certain value was at one time attributed, but which has since fallen into oblivion, is the appearance of the margins of the gums.

Some forty years ago Frédéricq directed attention to the presence, in various diseases, of a streak along the gingival margin which was of a different color from the surrounding mucous membrane. He described this streak as of a red color in acute phthisis, but of a more bluish tint in chronic cases. The streak was visible in the early stages, and the redder it was the more acute was the process, a diminution in the degree of redness being a favorable sign. A few years later Thompson described this same streak, which he said was seen less constantly in women than in men. The wider was the line the worse was the prognosis, according to this observer, and its absence in men justified a favorable opinion concerning the outcome of the disease. Later observers disputed the diagnostic and prognostic significance of this sign, and, like so many other little things in medicine, it was soon forgotten.

Recently Dr. G. Sticher had his attention called to the frequent occurrence of this line, and has examined upward of a thousand patients, suffering from various affections, with a view to determine its semeiological value. The results of this investigation, which he has published in the *Münchner Medicinische Wochenschrift*, No. 37, 1888, have led him to attach considerable importance to the sign. He found it almost constantly present in men suffering from pulmonary phthisis, and but very seldom in other affections. He does not wish to lay much stress upon it nor to regard it as pathognomic, but says that it is a symptom of some value, the more so because it is so easily determined by simple inspection. He found it present in pulmonary phthisis almost without exception, and, in men especially, it was one of the earliest signs of the disease, though in women, for some reason, it occurred much less constantly. It was never seen in men who were free from tubercular trouble, but in women it occurred sometimes during pregnancy and persisted occasionally for a certain period after delivery.

The author's conclusions were, that the presence of a red gingival line in men pointed strongly to the existence of pulmonary tuberculosis, but in women its value was much less. Similarly, its absence in women was of no diagnostic importance, but if it was not found in men there was a strong presumption that the affection from which they suffered was not incipient tuberculosis.

It is possible that this red line may be present in many or most cases of pulmonary phthisis, but its existence has been noted in other affections as well, and the diagnostic value which it is possible to attribute to it can hardly be very great.

THE AVERAGE COMPOSITION OF THE URINE.

THE composition of the urine varies slightly, as is well known, with the season, the diet, exercise, age, and sex. There is reason to believe, also, that racial differences exist. At any rate, it happens that most of the compositions given in standard works are of German origin, and may not apply strictly to other races. Vogel, Kerner, Drechsel, Mosler, among the Germans, have given tables of urinary composition; Beclard, Bouchard, Gautier, and others, among the French. Parkes has also made analyses of the urine of English adults. The figures of averages range, for total daily solids, from sixty to seventy-two grammes, showing a very considerable variation.

MM. Yvon and Berlioz have recently (*Rev. de Médecine*, September, 1888) reported the results of 661 analyses of urine, 347 being analyses of the urine of men; 314, of that of women. The specimens were all obtained from healthy adults, and, being made on so large a scale, with the greater conveniences and more complete chemical knowledge of to-day, seem to be worthy of special record.

The figures which the authors referred to give are these:

	Men.	Women.
Daily amount	1313.0	1125.0
Specific gravity	1022.4	1021.5
Urea	26.52	20.61
The range being	24 to 32	20 to 28
Uric acid	0.596	0.566
Phosphoric acid	3.191	2.590

The analyses did not cover the sulphates, chlorides, etc. They show a much smaller average for urea than is given by Kerner (38.1), Vogel (35.0), or Parkes (33.0).

It is noted that the different elements are all in greater proportion in the urine of man than in that of woman, with the exception of uric acid. The percentage of this in woman is 0.055; in man, 0.050. They establish a quantitative relation of 1 to 40 between uric acid and urea, a relation which is fairly constant. There is a decided difference, necessarily, between the ratio for man and that for woman.

For man it is	1 to 44.5
For woman it is	1 to 36.5
Giving the average	1 to 40.5

The relation of urea to phosphoric acid is also a constant one, the daily amount of urea being to the daily amount of phosphoric acid as 8 to 1.

News of the Week.

HOSPITAL SATURDAY AND SUNDAY ASSOCIATION.—This Association has begun to organize its preparations for the coming winter's collections. At a meeting held October 15th, the following interesting facts regarding last year's work were presented:

	1886.	1887.
Churches	$32,784 66	$28,626 79
Trades	12,740 82	14,276 85
Exchanges	2,709 05	3,104 06
Benevolent orders	726 50	640 50
Woman's fund	487 00	1,018 45
Personal and general	2,847 72	2,113 65
Professions	57 00	157 00
Box collections	699 23	511 85
Total	$53,051 98	$50,449 15

Following is how this was divided according to denominations:

From religious sources.

Denominations.	Designated.	Undesignated.	Total.
Episcopal	$2,273 29	$15,866 19	$18,139 48
Presbyterian	432 71	2,905 12	3,337 83
Methodist	1,182 37	689 18	1,851 55
Synagogues	....	1,679 14	1,679 14
Reformed Dutch	71 43	892 93	964 36
Congregational	5 56	695 00	700 56
Lutheran	353 94	274 33	628 27
Baptist	163 00	254 26	417 26

The Association gives a review of the events connected with the withdrawal of the Presbyterian Hospital, which shows, as has been shown before, the selfish and scheming policy of its managers.

THE UTERUS AS A CANDLESTICK.—In reference to the mutilation of the bodies of the women murdered recently in London, Dr. Block, a member of the Austrian Reichsrath (*Hospital Gazette*), directs attention to the fact that in various German criminal codes of the seventeenth and eighteenth centuries, as also in statutes of a more recent date, punishments are prescribed for the mutilation of female corpses, with the object of making from the uterus and other organs "thieves' candles" or "soporific candles." According to an old superstition, still rife in various parts of Germany, the light from such candles will throw those upon whom it falls into the deepest slumber, and they may, consequently, become a valuable instrument to the thieving profession. At the trial of the notorious German robber, Theodor Unger, surnamed "The Handsome Charley," who was executed at Magdeburg in 1810, it transpired that a regular manufactory had been established by gangs of thieves for the production of such candles. That this superstition has survived among German thieves to the present day was proved in a case tried at Biala, in Galicia, as recently as 1875.

THE FEVER AT JACKSONVILLE.—On October 29th there were reported 36 new cases and 4 deaths. The total number of cases up to date had been 4,095; deaths, 352.

CHLOROFORM AND ETHER.—A correspondent from Omaha asks if we see any reasons for changing the opinions often expressed regarding the use of ether as against chloroform. The facts, we would say, still remain strongly in favor of ether, and the tendency is toward its still wider use in Great Britain. There is some evidence of a reaction in favor of chloroform in this country.

THE TRAINING OF THE HANDS FOR THE ACQUIREMENT OF SURGICAL DEXTERITY.—Deftness and delicacy of touch are things which chiefly come by nature. Sufficient dexterity for most of the general surgical manipulations, however, can be acquired by training, and everyone can improve his natural gifts by practice. Mr. Ernest D. Bower, a London oculist, claims that playing on musical instruments, particularly the piano, gives strength and delicacy to the touch.

ANTISEPTIC TREATMENT "AS SHE IS DESCRIBED."—Dr. Von Mosetig-Moorhof, speaking at the Vienna Medical Congress, showed himself to be possessed of great originality in one thing—his bold and unique treatment of the English language. He quoted the following as Lister's statement of his "fundamental satze:" (1) "Let the wound to be alone;" (2) "Let the wound to be protected;" (3) "Let to the wound her free discharge." This interesting specimen of "English as she is spoke" by Sir Joseph Lister, will doubtless surprise many people; not least, we should imagine, Sir Joseph Lister himself.—*The Hospital.*

M. SUCCI began another thirty days' fast, at Barcelona, on September 22d.

IMPERIAL SYMPATHY.—Emperor William, as soon as he got back to Berlin, invited Von Bergmann and Gerhardt to dine with him, thus showing where his sympathies lie. While at Vienna he had a long interview with Professor Schrötter.

A MISALLIANCE WITH A PHYSICIAN.—American physicians will read with some interest and curiosity the following account of a matrimonial "misalliance" as given in the *Mail and Express:* "A misalliance often mentioned is that of the sister of the Duke of Westminster, Lady Alice, with Dr. Frank, a popular English physician at Cannes. Save in the mere matter of rank—and that, to quote Burns, is but the guinea's stamp—Lady Alice has made no misalliance. Surrounded by all the luxurious ease which wealth bestows, living in a climate which fills our dreams of heaven itself, and joined to a cultivated man of philanthropy and science, whose patients fairly adore him, the Duke's sister may well congratulate herself on having been brave enough to marry out of her order. So inexorable, however, are the decrees of English court caste that, were the children of Lady Alice the children of even the most worthless man of rank, instead of a noble-minded physician, their social status would be higher."

STATUS OF AMERICAN MEDICAL SCHOOLS IN EUROPE.—Dr. John H. Rauch writes as follows regarding the above subject in the *Medical and Surgical Reporter:* "Practically, the diplomas of no medical colleges are recognized in Europe. If the question was divided it could be answered much easier; as, for instance, the recognition of diplomas for the purpose of practice, or as a qualification prior to receiving degrees from institutions. Degrees of Harvard, University of Pennsylvania, and Bellevue receive recognition to a certain extent in some countries, but not in all. By a recent Act of Parliament the Medical Registration Law of Great Britain has been changed, allowing the registration of diplomas from other countries. I am not advised as yet whether the law has gone into effect, or what diplomas are recognized."

THE ETHICS OF JOURNALISM.—The premature publication by our contemporary, the *British Medical Journal,* of an analysis of Sir Morell Mackenzie's work, several days before its publication, and in spite of the most strenuous efforts on the part of publishers to prevent access thereto, has naturally given rise to much and severe comment. It is not unlikely that so gross a breach of the unwritten code of morality will lead to counsel's opinion being taken to ascertain whether the making of extracts to the extent of probably an eighth of the whole book, without comment, does not amount to a breach of the copyright law.—*Medical Press and Circular.*

REPORT OF A CASE IN WHICH, FROM CONGENITAL DEFORMITY, A MAN AGED FIFTY-FOUR HAS PASSED HIS FÆCES AND URINE BY THE URETHRA ALL HIS LIFE.—A case of the above character is reported in the *British Medical Journal* by Mr. Frederick Page. The patient, a small-built man of a peculiar, dark complexion, not unlike that of a person suffering from Addison's disease, was admitted into the Royal Infirmary, Newcastle-upon-Tyne, May 21, 1888, and gave the following history: Immediately after birth it was discovered that fæces and urine were passed from the meatus urinarius, and that the anus was imperforate. An attempt was made by a surgeon to establish an anus in the natural situation, but the operation was not successful; fæces and urine still passed by the urethra, though fluid has from time to time escaped from the anus. At the age of ten years the urethra became blocked by hardened fæces. Relief was obtained from an incision into the urethra immediately in front of the scrotum, and through the fistula thus formed the patient has continued, with great difficulty and discomfort, to pass his fæces and urine. He says he is in the habit of taking aperient medicine daily, and has to squeeze his fæces through the fistula with his fingers, the proceeding generally occupying from an hour to an hour and a half. From time to time the fistula has become blocked, and then the patient has passed his fæces and urine from the meatus. Sometimes, too, the urethra became blocked, and then the patient has passed his fæces through the fistula, and his urine by the fistula and from the anus, until he has succeeded in displacing the obstruction. His urine is generally clear and natural in appearance, but sometimes there is a brown deposit from it, and it has a fecal smell. He has been married twenty-four years, and is the father of one child.

Lanolin and Boric Acid in the Skin Diseases of Children.—The combination of lanolin and boric acid as an ointment is said to have a most gratifying effect in certain skin diseases in children, especially eczema of the head and face, intertrigo, and seborrhœa. In the case of eczema, for example, with raw patches on the cheeks and yellowish crusts on the head, the surface is first cleansed in the usual way, and then dusted over with finely powdered boric acid. On the following day this washing and dusting over is repeated; already the inflammation will seem lessened. The process is then repeated twice daily, the washing being always done gently, until the skin is in a condition to bear an ointment containing thirty per cent. of lanolin and eight per cent. of boric acid. In the squamous form of eczema with considerable induration, olive-oil is well rubbed in and then removed with Castile soap, and an ointment containing one-half, or one per cent., of salicylic acid with thirty per cent. of lanolin is energetically applied according to the degree of induration. This washing and application are repeated twice daily. The strikingly beneficial action of this course of treatment, which is less painful than the use of strong alkalies or oil of cade, is ascribed to the penetrating properties of lanolin, which thus facilitates the entrance of salicylic acid into the deeper layer of the epidermis. Dr. Russell Sturgis, who advocates the above treatment, also finds lanolin a reliable means of alleviating the irritation due to chronic urticaria.—*British Medical Journal.*

A New Method of Mixed Narcosis.—In a recent number of the *Wiener Klinische Wochenschrift*, Professor Obalinski proposes the following method of mixed narcosis, which he has repeatedly tried and found very useful. Pure chloroform is given, to begin with, in the usual way (that is, by means of Esmarch's mask), for from four to twelve minutes, the quantity of chloroform used being equal to from four to twelve grammes. A quantity of from three to five centigrammes of a three to five per cent. solution of cocaine is then injected into the place to be operated upon. There is no reason to be afraid of injecting even a larger quantity of cocaine, as chloroform, which is one of the best antidotes of cocaine, is administered at the same time; and also, because a part of the cocaine is removed by operation. After the injection of cocaine Professor Obalinski does not use any more chloroform, especially when the operation is one of short duration; occasionally he employs it in small quantities and at long intervals of time. The method has hitherto been employed in twenty-four cases, and the following are its advantages: 1. The advantages of both the general and local anæsthetizing methods are combined in it. Certain dangers proper to each of these methods are excluded by the combined procedure. The fact that a smaller quantity of chloroform is used gives greater confidence in its use, and besides, at the same time, a drug is employed which is known to be the best excitant, as it causes contractions of the blood-vessels as well as of the cardiac muscle, whereas chloroform paralyzes these organs. Again, there are individuals who have a certan idiosyncrasy in respect of cocaine; in these, even proportionately small doses of the drug produce disagreeable symptoms of cerebral anæmia, shown by tinnitus aurium, pallor of the face, giddiness, etc.; and an antidote, such as amyl nitrite, chloral hydrate, chloroform, ether, or morphine, when administered at the same time, instantly causes all these disagreeable phenomena to disappear. From all these facts it may be concluded that local cocaine anæsthesia, in connection with semi-narcosis produced by chloroform, is more reliable than pure chloroform narcosis. 2. Vomiting occurs much more rarely in mixed than in chloroform narcosis. 3. The patients awake more easily from the mixed narcosis, and do not feel depressed or weary. The sole disagreeable symptom —and it is one of rare occurrence—is that there is more excitement, especially in nervous persons. This is manifested by crying, uneasiness, or strong tetanic muscular contractions. Similar symptoms are, however, also observed in pure chloroform narcosis.—*British Medical Journal.*

Pyrodin: A New Antipyretic.—Dr. Dreschfeld has recently reported observations on a new antipyretic drug named pyrodin, the active ingredient of which was acetyl phenyl-hydrazin (*British Medical Journal*). This substance was a powder, which was very sparingly soluble in cold water; it had no unpleasant taste, and produced neither nausea nor vomiting. It acted much more quickly and powerfully than antipyrin, antifebrin, or phenacetin. It reduced the fever temperature within a few hours, and kept the temperature down for six or eight hours; this reduction was followed by a rise, and this was succeeded by a second fall, so that rarely more than one dose need be administered within twenty-four hours. The reduction of temperature was associated with sweating, but neither collapse nor rigor had been observed, though in some cases the reduction of temperature amounted to 7° F. The drug had been found especially useful in pneumonia, typhus, and scarlet fever; in typhoid fever the antipyretic properties were equally well marked, but slight toxic effects were occasionally noticed after a few doses had been given. The powerful antipyretic properties were also noticed in non-zymotic inflammatory fevers, such as peritonitis. It acted well also in cases of migraine, even when antipyrin failed. Given in repeated doses of eight to twelve grains, pyrodin was apt to produce toxic effects; these consisted in the appearance of jaundice, due to commencing hæmoglobinæmia, as was proved by a series of experiments on rabbits. The dose of pyrodin for children was three to four grains, for adults eight to twelve grains.

For the Removal of Freckles a lotion composed of equal parts of lactic acid and glycerine is said to be efficacious.

Society Reports.

CANADIAN MEDICAL ASSOCIATION.

Twenty-first Annual Meeting, held in Ottawa, September 12 and 13, 1888.

(Special report to The Medical Record.)

WEDNESDAY, SEPTEMBER 12TH—FIRST DAY.

THE Twenty-first Annual Meeting of the Canadian Medical Association was held in the Parliament Buildings, Ottawa, and was largely attended by medical men from different provinces of the Dominion.

DR. J. E. GRAHAM, of Toronto, the retiring President, delivered the

ADDRESS OF WELCOME.

He said he thought they might congratulate themselves upon the prospect of having a pleasant and profitable meeting, and they could the more confidently do so seeing that they had selected as President, this year, a gentleman in every way capable of fulfilling the duties of that office; one who was a leader of his profession in one of the largest cities of the Dominion, and whose reputation is not alone confined to that city, but to the Dominion at large. He took great pleasure in introducing Dr. George Ross, of Montreal, the President-elect.

CHAIRMEN OF SECTIONS.

After the election and introduction of a large number of new members, the President appointed the chairmen of the different sections as follows: For the Medical Section, Dr. Bray, of Chatham; for the Surgical Section, Dr. Cameron, of Toronto; for the Obstetrical and Gynæcological Section, Dr. Trenholme, of Montreal.

DR. GIRDWOOD, of Montreal, read a paper on

RECIPROCITY OF REGISTRATION.

He stated that on making inquiry in regard to this subject on a recent visit to England, he had been informed that before registration could take place it would be necessary to have an Order in Council passed making a new law of reciprocity of registration, applicable to Canada. Reciprocity takes place between Great Britain and Australia, and he thought that we might very fairly have reciprocity of registration between Great Britain and this colony. He remarked upon the marked want of harmony existing between the medical councils of the different provinces, in not allowing members to practise in every province of the Dominion of Canada. He proposed that a committee be appointed to make inquiries and ascertain the views of the different provincial societies on the matter, so that, if possible, steps might be taken to secure the desired end. After a spirited discussion the resolution was adopted.

DR. GEORGE ROSS, of Montreal, then delivered

THE PRESIDENT'S ADDRESS.

He first commented on the extraordinary progress of the Dominion, and pointed out the activity in all branches of science and learning. There had been, during these years of progress, an almost entire revolution in the science of medicine, and in the methods adopted for teaching the same. Preventive medicine has occupied a place to which its importance justly entitled it, and sanitary laws and regulations were attracting the attention and occupying the minds of statesmen. Never was there a time when more attention was being given to the enforcement of sanitary laws and the diffusion of sound sanitary knowledge. In regard to medical tuition, instead of the old fashion of walking the hospitals, systematic attendance at wards was being insisted upon. He approved of the development in regard to specialists, and held that the whole profession had been a gainer by the work of such men, and the good counterbalanced, to a great extent, the objections urged, that specialties were overdone, or were being cultivated by unworthy members. He advocated the establishment of a Dominion Annual Register at Ottawa, so that a regularly qualified graduate in medicine might, by registering therein, be permitted to practise medicine throughout the whole Dominion, without prejudice to the official bodies in the different provinces. He claimed for this Dominion Medical Association a share in bringing about the improved state of things in the present day. Although they failed to carry out such comprehensive measures as were advocated at first, they had been occupied in considering matters of general hygiene, and the discussions at their meetings had been instrumental in the carrying into effect of legislation which promoted the public health. He deprecated the

LAXITY OF THE OFFICIALS

in a city not very far from Montreal, where typhoid fever was prevalent, and their hesitation in trusting to experienced practitioners, whose efforts would do much to alleviate the ravages of the outbreak. It was a reflection upon our sanitary organizations that such things could be, and that no efforts were made to eradicate the evil as soon as discovered. The matter of alleged cases of malpractice was alluded to, and the severest condemnation was expressed for the unworthy members of the profession who originated and fomented such actions. He regretted the small attendance of their French-Canadian brethren, but hoped their interest in the Association would increase in the future. In making reference to the necessity of every medical man seeking every year some recreation, he praised a trip to the Northwest and British Columbia as likely to greatly invigorate the jaded physician. He had recently visited the latter province, and had found the sulphur springs at Banff, in the Rocky Mountains, entitled to the highest praise. After alluding to the desire on the part of many of the members to hold their next meeting at the Banff Springs, Dr. Ross concluded his admirable address by referring in fitting terms of respect to the demise of several talented members of the Association during the year.

DR. WORKMAN, of Toronto, moved a vote of thanks to Dr. Ross for his able address.

SIR JAMES GRANT, of Ottawa, in supporting the motion, said he was very glad to have the opportunity of listening to the admirable address delivered by the worthy president, Dr. Ross, of Montreal, and it was to him a matter of great pleasure to see present the mover of the resolution, Dr. Workman, now in his eighty-fourth year. It is a fitting recognition to our Association, to have here to-day Dr. Workman, so well known, not only in the Dominion of Canada, but throughout the length and breadth of the world, to move to Dr. Ross a vote of thanks for the masterly address delivered.

DR. SWEETLAND, of Ottawa, on behalf of the local Medical Association, then extended a hearty welcome to the visiting members of the profession, and assured them that they would receive that hospitality at their hands which is customary among medical men wherever they may meet.

DR. F. J. SHEPHERD, of Montreal, delivered an address entitled

RECENT ADVANCES IN SURGERY.

He said that the history of surgery during the past fifty years had been one of continuous progress, and had proved the falsity of Boyer's opinion, expressed after the French war, that "Surgery seems to have attained the highest degree of perfection of which it is capable." The advances made in the last decade might be considered phenomenal, and now scarcely a month passes without the introduction of some new operative procedure, or some daring operation, in cavities and organs which have from time immemorial been regarded as sacred. The causes of this advance have been two in number, the discovery of anæsthesia and the introduction of aseptic surgery, with which the name of Lister will ever be associated. Formerly surgery was regarded as a mechanical art, and practitioners of medicine looked down upon the surgeon as one who practised a trade. How different is the relationship now! Surgery now takes the lead, and the surgeon has wrested from the physician many regions which he thought to be essentially his own. The abdomen, for a long time the hunting ground of the physician, has been almost completely surrendered to the surgeon, and with what brilliant results every one knew. Certain diseases of the liver, kidneys, ovaries, brain, etc., which were formerly purely medical, have become chiefly surgical, and owing to modern methods of operative treatment many lives have been saved which heretofore the physicians let slip through their fingers as being beyond their skill to cure, though they endeavored by a copious and, it is to be hoped, judicious use of the various preparations in the Pharmacopœia, to alleviate the sufferings of their unfortunate patients. The brain, within the last few years, has yielded not a few results to surgery which medicine has striven for in vain. Still, medicine and surgery are not opposed to one another, and should go hand in hand. Without the aid of the physician many cases would escape the beneficent treatment of the surgeon; and one cannot afford to do without the other. As Bergmann had said in his address before the German Scientific Medical Association, in 1887, "There is more or less rivalry between medicine and surgery in the cure of disease, but further progress in surgery can only take place through an increased knowledge of internal medicine. Surgeons must now avail themselves more of the accurate means of investigation which we owe to physicians—auscultation and percussion, thermometry, chemical, microscopical, and electrical investigation. As long as internal medicine remains the guardian of scientific methods and scientific principles, so long will it remain the parent tree of which surgery is only the branch. There is a

DANGER OF SURGERY DEGENERATING INTO A MERE DISPLAY OF MANUAL DEXTERITY,

and one is struck, in reading the surgical literature of the day, by the almost exclusive attention paid to the operative aspects, while those departments of surgery which are not operative receive but scant consideration. Alluding to some of the recent advances in the more important departments of surgery, reference was first made to the progress gained in the treatment of wounds by the careful attention paid to cleanliness, rest, and asepticism. Faith in germicides is now being lost, and although irrigation has supplanted the spray, the solutions have become weaker and weaker, until some surgeons use water only, especially in operations on the abdomen or thorax, where antiseptics have proved to be absolutely injurious, and often dangerous; while in Germany, lately, he had seen in every surgical klinik the magnificent ruins of the spray producer, looking like some old castle which marked the customs and conditions of other days. In cases of

ACUTE INTESTINAL OBSTRUCTION

it is now becoming a recognized custom for the physician to call in a surgeon in consultation, and the result was that many lives had been saved by timely surgical interference. It is now an axiom of surgery not to let any case of acute intestinal obstruction die without at least an exploratory incision. In inflammations of the cæcum and appendix surgical interference had been attended, in numbers of cases, by remarkable success. In tubercular peritonitis most brilliant results have been effected by operation. The same can now be said in regard to cases of suppurative peritonitis. American surgeons are the leaders in operations in perforating gunshot wounds of the abdomen.

THE RADICAL CURE OF HERNIA

had been much discussed of late, and at the Dublin meeting of the British Medical Association several valuable contributions had been made to show the gradual progress being made in that department. Dr. Shepherd related an interesting and successful case, in which he had lately operated by excision of the sac and fixing the stump at the internal ring. In the victorious advance of surgery the liver has not escaped. The left lobe has been successfully resected, and several surgeons have sutured the liver with success for gunshot and other wounds. The surgery of the gall-bladder had been making steady and uninterrupted progress, and its excision has been frequently performed with success. After reference to the advances in surgery of the kidney, bladder, and stomach, the paper concluded with a concise review of the progress made in the surgical treatment of the various diseases and

INJURIES OF THE BRAIN AND SPINAL CORD.

Brilliant results have been obtained in this department, results which, a few years ago, would have been looked upon as utopian. While the operation of trephining the skull was an old one, it was long thought unsafe to venture beyond the dura mater, and highly injudicious to interfere with the brain itself; and it was only with the introduction of antiseptic surgery, and a more accurate knowledge of the localization of brain functions that the brain had been interfered with. But the observations of brilliant investigators have proved that many areas in the brain are connected with separate and distinct functions. It was found that if these areas on the surface of the convolutions were stimulated electrically, distinct movements were excited in different groups of muscles on the opposite side of the body. Since the truth of the theory of Broca's localization has been established on a firm basis, operations have been undertaken where there was no external indication of injury or disease. The lesions have not only been successfully diagnosed, but the brain and its membranes have been incised without resulting in fatal inflammation. It has been clearly shown that inflammatory conditions following operations are due to sepsis. The achievements of Macewen and others in surgery of the spinal cord were commented upon, and the admirable address concluded with a brief summary of several other advances indicating the progress of modern surgery.

MEDICAL SECTION.

DR. T. W. MILLS, of Montreal, presented a paper on

THE INFLUENCE OF THE NERVOUS SYSTEM ON THE NUTRITIVE PROCESSES.

He began his address by referring to a synopsis of a paper read by him last year, on a new basis of improved cardiac pathology, which developed the theory that all the nutritive processes were constantly under the influence of the nervous system. He explained metabolism as the molecular life of protoplasm, and regarded the organic action of the nervous system, or nerve with the tissue element, as regulating these processes. He proved that nerves going to bone, on being divided, caused atrophic changes in the bones; a change called by Charcot acute necrobiosis. He also referred to certain affections of the skin following nerves, which he traced to similar nervous lesions. He spoke of the cause of death in animals after section of the vagi nerves as being due to pneumonia, which was an inflammatory process due to the severance of the nerve connection. In birds, section of nerves in connection with the heart was followed by its fatty degeneration. He discussed the influence of the trigeminus nerve, also the inhibitory fibres and sympathetic fibres, due wholly to such interference with nutrition. He referred to the emotions, and their influence on vital processes as being such, and also dwelt upon the training of athletes, stating that over-exertion called into play, and used up, the residual nerve-force.

The paper was discussed by Drs. Sheard and Graham, of Toronto, Drs. Small and Playter, of Ottawa, and Dr. Campbell, of Montreal.

SURGICAL SECTION.

Dr. **Proudfoot**, of Montreal, read notes of a case of

EXCESSIVE HEMORRHAGE, AFTER CATARACT EXTRACTION, INTO THE ANTERIOR CHAMBER OF THE EYE.

No anæsthetic was used, and no iridectomy made. Pressure was made over the globe by compress and bandage, which were removed next morning owing to great pain, and an atropine solution dropped into it. Hemorrhage continuing, pressure was reapplied with boracic acid solution, and morphia given for the pain, which was very severe. Hemorrhage continuing on the eleventh day, enucleation was performed, and on dividing the globe, the point from which the hemorrhage came was found to be in the retina. No reason could be given for the troublesome hemorrhage, excepting that the patient was very plethoric and a drunkard.

OBSTETRICAL AND GYNÆCOLOGICAL SECTION.

Dr. **Alloway**, of Montreal, read a paper on

THE INDICATIONS FOR, AND COMPARATIVE MERITS OF, EMMET'S AND SCHROEDER'S METHODS OF OPERATING UPON THE CERVIX UTERI.

This paper gave rise to an interesting discussion on the subject.

Dr. **Gardner**, of Montreal, was in favor of Schroeder's operation as compared with Emmet's, in cases of extreme hypertrophy of the cervix, and inflammation of the mucous membrane. He considered it enabled disease to be removed where Emmet's fails, on account of the stitches being unable to approximate the edges together after an operation.

Dr. **Trenholme**, of Montreal, favored Emmet's operation in all cases, except in very extreme ones of hypertrophy and inflammation accompanied by glandular condition of the follicles, where Emmet's operation was not available, but thought that in very few cases would this be found necessary, if the tissue was pared away well toward the cervical canal, leaving a narrow border by which tissue could be obtained. Pressure upon the hypertrophied parts afterward would lead to the formation of the natural cervix. In no case were we warranted in amputating the cervix if it could be avoided.

The discussion was largely in favor of Schroeder's operation being resorted to only in extreme cases.

THE ANNUAL BANQUET

of the Association was held in the evening at the Russell House, and was largely attended.

Thursday, September 13th—Second Day.

After the meeting had been called to order, Dr. Ross, the President, introduced Dr. G. H. Oliver, delegate from the Medical Society of the State of New York, Dr. Wallis Clark, of Utica, N. Y., and Dr. Imrie, of Detroit, Mich. They were received most cordially.

Dr. W. H. Henderson, of Kingston, President of the Ontario Medical Association, was also introduced, and in pleasing terms referred to the feeling existing between the parent association and the provincial body of which he had the honor to be the head.

The report of the Committee on Nominations was then presented and unanimously adopted. It recommended

THE ELECTION OF OFFICERS

as follows:

President—Dr. H. P. Wright, Ottawa; *Secretary*—Dr. James Bell, Montreal; *Treasurer*—Dr. W. H. B. Aikins, Toronto; *Vice Presidents*—For Ontario, Dr. C. Sheand, Toronto; for Quebec, Dr. F. W. Campbell, Montreal; for New Brunswick, Dr. Graham, Bathurst; for Nova Scotia, Dr. E. Farrell, Halifax; for Manitoba, Dr. Lynch, Winnipeg; for British Columbia, Dr. J. M. Lefever, Vancouver; for Northwest Territory, Dr. Jakes, Regina; for Prince Edward Island, Dr. Jenkins, Charlottetown.

The Committee recommended that the next annual meeting be held at Banff Springs, in the Northwest Territory, not later than the second Wednesday in August, 1889. The Canadian Pacific Railway Company sent a communication to the effect that transportation tickets, including sleeping-berth and meals, from any part of Ontario or Quebec to Banff and return, would be issued for $95, and they would board the delegates free of cost for four days at the hotel at Banff Springs. The distance from Montreal to Banff and return is 4,684 miles.

A cordial vote of thanks was accorded to Dr. Charles Sheard, of Toronto, for his long services as treasurer of the Association, an office from which he requested permission to retire.

The meeting then adjourned to meet in sections.

MEDICAL SECTION.

Dr. **J. E. Graham**, of Toronto, read a paper on

A CASE OF EXTREME RAPIDITY OF THE HEART'S ACTION,

which was briefly discussed by Drs. Mullen, of Hamilton, Mills, of Montreal, Sheard, of Toronto, and Milne, of Victoria, British Columbia.

Dr. **R. P. Howard**, of Montreal, read an interesting paper on

OPHTHALMOPLEGIA EXTERNA,

illustrated by diagrams. He spoke of a case of ophthalmoplegia externa and interna, and explained as a cause the close association of the cerebral centres and the extension of the disease from these. He referred to cases recorded where both ophthalmoplegia externa and interna had been caused by hysteria. He noted also the association of this condition with locomotor ataxia and pseudohypertrophic muscular paralysis. He was convinced, however, that ophthalmoplegia externa could exist without such association. He also discussed the relation of syphilis to this ocular disease.

Drs. Stewart, of Montreal, Mullen, of Hamilton, Graham, of Toronto, and others discussed the paper.

Dr. **Playter**, of Ottawa, read a paper on

A FEW FACTS RELATIVE TO COMMUNICABLE DISEASES IN MAN AND ANIMALS,

especially as brought out at the recent Paris Congress and British Medical Association, referring particularly to tuberculosis.

SURGICAL SECTION.

Dr. **Fenwick**, of Montreal, presented a paper on

RETROPHARYNGEAL TUMORS.

In these cases the operation must be regarded as formidable, and the literature on the subject was scant. Dr. Cheever, of Boston, Mass., appeared to have been the first who operated on these tumors. Velpeau operated in 1836 on a large tumor, operating by the mouth, tying the artery first. The patient died on the seventeenth day. Dr. Fenwick was early convinced that operation from the outside is the correct method. These tumors are usually sarcomatous or cancerous, and in a large majority of cases recur. Dr. Fenwick then proceeded by diagrams to illustrate Dr. Cheever's method of cutting from without. A long straight incision is made, beginning on a level with the lower border of the ear, and extending down the neck in the line of the great vessels. If sufficient room is not thus given, he makes a transverse incision from the straight incision across the jaw. The jaw is not divided, the vessels and nerves are drawn aside, and the tumor enucleated in the usual way. Czerny's operation is modified from Cheever's. He opens the trachea and keeps up respiration in this way during the operation. He divides the jaw-bone between the second and third molar, and in getting down to the tumor has to sacrifice the chief nerves and vessels in that region. He then removes the tumor with a hot knife. Dr. Fenwick then described his own operation by a curved incision following tolerably well the line of the angle of the jaw. In two cases the operation was easy, no vessels or nerves of importance were divided, except the facial nerve in one case. The bleeding in both cases related was practically nil.

Dr. **Sheard** thought that distinction ought to be made between cancerous and sarcomatous tumors. He thought cancerous tumors, which were not neglected, required a more serious operation, and that more room should be given, as they could not be removed solely with the finger without dissection.

Dr. **Bell**, of Montreal. read a paper on

EXOSTOSIS BURSATÆ,

in which he gave the notes of a case which he believed to be the only one reported by an English-speaking surgeon.

Dr. **Shepherd**, of Montreal, referred to the great rarity of the disease, and drew attention to the explanation which was offered, of the existence of floating cartilages in the joints.

Dr. **Buller**, of Montreal, then made a few remarks on

PENETRATING WOUNDS OF THE EYEBALL,

and related several interesting cases where the urgency of prompt treatment and cleansing the wound had been advantageous.

Dr. **Shepherd**, of Montreal, followed with a paper on

MANIA FOLLOWING OPERATIONS,

and reported six cases in which he attributed mania to the use of iodoform.

Dr. **Stirling** read a paper on

SOME EYE-SYMPTOMS DUE TO CEREBRAL LESIONS.

This was followed by two papers by Dr. **Lapthorn Smith**, of Montreal. The first on "The Treatment of Varicocele and Orchitis by the Electrical Current of Tension;" the other on "A Case of Resilient Stricture of the Urethra Cured by Electricity."

OBSTETRICAL AND GYNÆCOLOGICAL SECTION.

Dr. **Smith**. of Montreal, presented a paper on

SOME MINUTE BUT IMPORTANT DETAILS IN THE MANAGEMENT OF THE CONTINUOUS CURRENT IN THE TREATMENT OF FIBROID AND OTHER DISEASES OF THE UTERUS.

He insisted upon attention being paid to antiseptic treatment, and upon performing all the operations with care. The results in his own hands had been very satisfactory. He recommended the electrode of Dr. Inglemann in preference to Apostoli's clay electrode. The different forms of electrodes of sounds were shown, and that of Martin he favored most, as being the least expensive, and at the same time serving the purpose. He referred to the necessity of exact dosage, and the after-care of patients where much electricity had been used.

This paper led to an interesting discussion as to the field for which it was intended to be useful.

Dr. **Trenholme**, of Montreal, favored an antiseptic method apart from irrigation, simply advising that the vaginal passage be washed out with soap and water. and a plug of antiseptic cotton left in contact with the cervix, when the sound was removed.

After the meeting of the sections had been concluded, a general session of the Association was held.

PRECAUTIONS TO PREVENT TUBERCULAR DISEASE.

Dr. **Milne**, of Victoria, British Columbia, moved, and Dr. **Sweetland**, of Ottawa, seconded, the following resolution, which was unanimously adopted:

"That in view of the apparently increasing prevalence of tubercular disease in domestic animals, more especially in cows, it is the opinion of this Association that it is desirable that some legislative action should be taken by the Dominion Government to check the progress of this disease, and we urge that the Government take this matter under their consideration at as early a date as possible."

Votes of thanks were passed to the retiring officers of the Association, the medical profession of Ottawa for their generous hospitality, and to the Government for the use of the Committee rooms of the Parliament building.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN PRACTICE OF MEDICINE.

Stated Meeting, October 16, 1888.

R. C. M. **Page**, M.D., **Chairman**.

Dr. **Landon Carter Gray** read a paper on

NEURASTHENIA; ITS DIFFERENTIATION AND ITS TREATMENT.

Dr. Gray first directed attention to the fact that functional nervous diseases are largely disregarded by the general practitioner because of the modern development of the study of them, although the need of a classification of them was widely felt, especially by neurological specialists. For this reason it was that the writings of Dr. George M. Beard had had such a success in Germany. Dr. Gray did not believe that true neurasthenia was as prevalent as the followers of Beard would have us believe. He stated that, in his opinion, there were three forms of neurasthenia: the reflex, the lithæmic and the simple. The reflex form was due to vicious habits and reflexes from non-nervous organs, the lithæmic was due to lithæmia, and the simple form was that in which there was true nervous prostration. The points of differential diagnosis of these various forms were then dwelt upon. But neurasthenia was also to be differentiated from a number of nervous diseases, especially the early stages of the latter, such as the morbid fears (for which Dr. Gray suggested the name of functional insanity), and which really belonged to the insanities and were often associated with them; melancholia, especially the mild forms, in which suicide was often committed; the early stages of mild chronic forms of insanity; neurotic individuals who are subject to migraine, hysteria, angina pectoris or anginoid attacks; the early stages of general paresis of the insane, of locomotor ataxia; and a peculiar disease described a year ago by Dr. Hughes Bennett, and called by him muscular hypertonicity, in which the symptoms are those of weakness and exaggerated reflexes of the lower extremities.

The prognosis of these different forms was variable, depending upon the severity of the reflex cause and the possibility of thorough treatment. The treatment of the reflex form was the removal of the cause, if possible. The lithæmic form was to be treated by moderate laxatives, dilute nitro-muriatic acid, and, if the nervous symptoms were severe, by rest. In any case rest was a most important adjuvant, and should be proportioned to the needs of each case, it being better to have rather too much of it than too little. The diet should be regulated to a moderate degree by the cutting off of starchy and nitrogenous material for a short time, and then by the cutting down of the starchy material permanently by at least fifty per cent. In hot weather it was sometimes advisable to cut off the nitrogenous material for several weeks. In the true cases of neurasthenia the best treatment was that advocated by Dr. Weir Mitchell, of rest, forced food, massage, and faradism. Large doses of iron and malt extract should also be given in this treatment, with which the great difficulty was, however, that patients are apt to be disappointed at the loss of their muscular strength upon first getting out of bed. It should be explained to them that this would gradually return. Great care was necessary, however, with many patients at this period, to prevent them from losing the flesh and red blood that had been gained. Galvanism is an agent of great value in all these forms of neurasthenia, and should be used as early as possible. except when the case is to be put to bed. It should be applied by large sponges, one in the nape of the neck, the other in the dorsal spine, five to fifteen milliampères of electricity being used, and the sitting every day for three to five minutes. Massage was an uncertain remedy, often irritating the patient.

Dr. N. E. Brill thought the author had again demonstrated the fact that whatever work he did. he did it well, and with his accustomed literary ability. He did not hesitate to express the opinion that if Dr. Beard had not attempted to concentrate certain nervous phenomena which he could not explain on physiological or pathological grounds into a symptom-group, that neurasthenia would not have been elevated to the dignity of a disease. The mere fact that the Germans had accepted Dr. Beard's views had tended to perpetuate the term and to give rise to considerable writing at the present time. They had said, and doubtless with truth, that they could find nothing in Germany identical with the affection as described by Dr. Beard. Neurasthenia, as the term implied, was simply an exhaustion of the nerve-centres. This might be due to anything which would derange the physical state. Thus we saw it in diarrhœa, diseases of the stomach, and of other organs. If peripheral or internal diseases continued a long time, the nervous impulse transmitted from the diseased organs was likely to exhaust the nerve-centres to the extent of producing neurasthenic symptoms. or a multitude of nervous symptoms.

Dr. Eugene C. Reeves, of St. Paul, remarked that in the West they made little excuse for errors in diagnosis by Eastern men, whose opportunities for observation were much better than their own. To be a good diagnostician of neurasthenic conditions one had to be a good clinician. He recalled one case in which the diagnosis of neurasthenia had been made, and when he was called he was able to correct the error and point out cerebral apoplexy by the presence of aphasia. In another case, however, in which he had diagnosticated neurasthenia in a woman, his colleague subsequently observed a tumor, apparently of the great vessels in the abdomen, supposed to be cancerous. The patient died, and at the autopsy the apparent tumor was found to be due to a forward bend of the spinal column, which was unduly prominent from emaciation. No cause for death was discovered. He thought the molecular disturbance caused by railroad concussion might give rise to a neurasthenic state, and in time perhaps lead to degenerative changes. In treatment, he had obtained good results from methods directed against malnutrition of the nerve-centres. But in forms of circulatory disturbance, with an undue amount of blood in the head, benefit had followed bromides and ergot, though the administration of these should not be continued too long. In the so-called spinal form of neurasthenia he had obtained the best results from galvanism. Then, contrary to what seemed to have been the experience of neurologists in New York, he had found static electricity of value.

Dr. W. R. Birdsall had found the term neurasthenia a puzzle. He did not know whether it should be used at all. When he applied it to a group of symptoms he felt that he was rather trying to cloak his ignorance in the case. Yet we must admit a neurasthenic element in certain diseases; but in applying the term neurasthenia to a group of symptoms it nearly always failed to fully cover the conditions present. In functional troubles among certain persons there was a predominance of nervous symptoms, a fact frequently depending on a peculiar instability of the nervous system of inherited origin. If the term neurasthenia were used in its limited sense this would be the class of patients to which it should be applied. But there were cases in which the fault in the nervous system might be acquired, and here local causes, as refractive errors in the eye and defective muscular states, might cause neurasthenic symptoms. In some, removal of the local condition would cause the nervous symptoms to disappear. while in others it would not. The classification made by Dr. Gray, of lithæmic and reflex cases of neurasthenia, seemed to be a convenient one, but, not having heard the third class described, those of simple neurasthenia, he could not express an opinion. The lithæmic form probably took in the greater number of cases. In treatment, the question of rest and exercise would have to be solved in each particular case, for sometimes more exercise of one kind was needed and less of that commonly taken; some patients required one form of rest, others another form. Walking on the level was not sufficient; it should rather be mountain climbing in congenial company. Excesses, particularly sexual, were often a cause of neurasthenia.

Dr. W. H. Thompson thought the term neurasthenia was a very satisfactory one to use before patients, for when pronounced slowly and distinctly it made a strong impression upon their minds; but in medical science it was to be abominated. It was on the same level with the term tonic in therapeutics, which might include arsenic, strychnine, electricity, sea-baths, etc., agents which acted in very different ways. Words taken up without conveying a definite meaning were likely to lead to many errors. When he was unable to attribute a given case to a definite disease he asked himself these questions: Is this a case of nervous debility or one of virtual starvation? Is it a case of over-strain, or is it one of self-poisoning? In a good many patients it would be found that while they were taking three meals daily, yet the food was not of an amount or character to prevent virtual starvation with resulting neurasthenic symptoms. A common form of over-strain was that which arose from excessive worry. In the former cases proper food was required, while in the latter sleep should be secured, together with new and pleasant surroundings. In some the symptoms were due to a drain on the system, like excessive venery, to which Dr. Birdsall had referred. Regarding self-poisoning, it was only recently we were turning back to a part of the system which our forefathers had recognized as the starting-point of many ills, namely. the bowels. Here, were it not for the preservative effects of healthy function, constant opportunity would be afforded for decomposition and for poisonous elements to enter the circulation. It was in cases of prolonged auto-intoxication that a complexity of symptoms arose to which Dr. Gray had given the name lithæmic neurasthenia. But how were we to distinguish cases of starvation and over-strain from those of self-poisoning? It was by the character of the pulse and urine. The pulse in the former class was uniformly very weak and compressible, and the urine of low specific gravity and ordinarily neutral or alkaline; while in the other class the pulse was of high tension, the artery distended, while the urine, unless the kidneys had already begun to suffer, was of high specific gravity, at least at times during the day, and was acid or contained a larger amount of urates. In the lithæmic class there was one remedy which had not failed to effect a cure, namely, camping out. Nomadic tribes did not suffer from gouty symptoms or the lithæmic state. More air was required than these patients were accustomed to at their homes and business.

Dr. A. Jacobi thought Dr. Gray had made a historical mistake, for more than one writer on the continent had described conditions now recognized as neurasthenia before Dr. Beard wrote, consequently the disease so called could not be peculiar to America The fact that Americans had been called a peculiarly nervous people had also led at one time to the supposition that infantile paralysis existed only here, and Dr. Beard had even claimed hay fever as an American disease. The name neurasthenia pointed to a complexity of symptoms, the cause of which should be sought. The term neurasthenia should be abandoned.

Dr. A. D. Rockwell believed in the term neurasthenia; he believed in it as much as he believed in that of malaria. He agreed, however, with those who thought its use had been abused very much. To him there was a marked distinction between the neurasthenic condition and nervous exhaustion.

Dr. S. Baruch also believed that there was such a disease as neurasthenia, or rather a complexity of symptoms to which that term could well be applied. He also believed in tonics, and that of the cold plunge as beneficial in many of the neurasthenic cases.

Dr. E. D. Fisher thought the term neurasthenia was the best we yet had for expressing a given group of symptoms. Inasmuch as it represented function rather than pathological changes, as far as was yet known, the treatment would consist largely in measures intended to improve nutrition. One of his favorite prescriptions in this class of cases was nitro-muriatic acid, combined with Fowler's solution, or tincture of nux vomica, and, contrary to the rule just given by Dr. Jacobi, he had administered it with the greatest advantage before meals.

Dr. Gray closed the discussion. He thought there was little difference between his standpoint and that of the speakers. If one had all medical knowledge at command he might be able to exclude certain cases, now classed among the neurasthenias, because due to a definite pathological lesion; yet even with that amount of knowledge some cases would remain, which, so far as could be determined, had no permanent pathological basis, but rather were functional, and would still require a group-name, such as neurasthenia. He mentioned three cases, not in his own practice, in which the diagnosis of neurasthenia was made, and weakness progressed and terminated fatally, yet the autopsy failed to explain death.

Gigantic Intestinal Diverticulum.—Dr. Maas, of Wurzburg, has published a remarkable case of abdominal tumor. The patient was a boy aged fourteen. Shortly after birth the abdomen began to swell; the tumefaction increased as years passed by, with little disturbance to the system, till one year before inspection; then the swelling became much larger, and the lad suffered from dyspnœa and palpitations. The urine was normal; the bowels were often moved; the stools were scanty and thin. The abdominal walls were very tense but not œdematous, the skin pale; some of the subcutaneous veins were uniformly dilated. The circumference at the umbilicus was thirty-five and a half inches; three inches higher, the point of greatest distention, the girth was over thirty-nine inches. The resonance was uniformly tympanitic, with very slight impairment laterally. No solid tumor could be felt. The urine was albuminous on the first day, but not subsequently. Much fæcal matter was voided after injection. A sound passed into the rectum could be felt under the parietes, apparently over the tumor. On that account congenital hydronephrosis on the left side, or cystic degeneration of the kidney, was diagnosed. An exploratory puncture was made in the left loin with a somewhat large trocar. Only fæces escaped. An incision was then made along the linea alba. A large plexus of thick veins covered the surface of the suspected tumor; the operator feared to proceed further, so the abdominal wound was closed. It then appeared as though a cystic kidney, communicating with the intestine, existed. No peritonitis ensued, but the swelling increased, and after suffering badly from dyspnœa, the boy died suddenly. The tumor proved to be a gigantic diverticulum, from the upper part of the rectum; it was filled with fourteen litres of thin fæces, and also contained gas. The aperture of communication, the diameter of which was not mentioned in the *Centralblatt*, was at the posterior inferior aspect of the diverticulum. The rectum was strongly compressed by the tumor. Kölliker and Maas attributed the malformation to a disturbance in the normal involution of the layers of the blastoderm.—*The British Medical Journal.*

Correspondence.

CONCERNING THE SO-CALLED SPECIFIC FORM OF YELLOW FEVER.

To the Editor of The Medical Record.

Sir: I had not intended to pay any attention to Dr. Freire's recent publication, in which he makes a desperate effort to sustain his previous claims in the face of overwhelming evidence showing them to be without foundation; but as you have called attention, in your editorial in The Medical Record, October 6, 1888, page 426, to the manner in which he has attempted to dispose of my evidence, I have thought it best to make a brief statement of facts for the benefit of your readers. As an introduction to what I have to say I quote from your editorial referred to:

"Dr. Sternberg is dismissed in a foot-note, in which Dr. Freire says that the American sojourned but a short time in Brazil, at a time when there was no epidemic; he examined but one sporadic case and made no autopsy."

It is true that my orders took me to Brazil during the non-epidemic season, and that I was not able to secure an autopsy while there, but it is not true that I only examined a single case. I had an opportunity to make cultures from blood drawn from the finger in five typical cases which occurred in the city of Rio de Janeiro soon after my arrival, and in none of them did I find Freire's *cryptococcus xanthogenicus*, either in my cultures or in stained preparations of the blood.

It was a matter of great regret to me that I could not secure any autopsies while in Rio, but I was not sent to that city for the purpose of making clinical or pathological studies of yellow fever. The special object of my mission was to investigate the method and results of Dr. Freire's inoculations, and to ascertain the nature of the material with which they were made.

I had as much time—over two months—as was necessary for the accomplishment of this object, and made a thorough investigation, the results of which are embodied in a detailed report which I submitted to the President of the United States several months since.

I show conclusively in this report that there is no scientific basis for Dr. Freire's claim that he has discovered the specific cause of yellow fever, and no satisfactory evidence that his inoculations have any prophylactic value. When this report is published I do not doubt that the profession will accept the conclusions here stated as established by it.

It is true that when I went to Brazil I had already formed an opinion which was not favorable to Dr. Freire's claims, but this did not prevent me from investigating them in an impartial manner. My opinion was based upon my own extended researches, made in Havana, as a member of the Yellow Fever Commission of 1879, and upon a perusal of Dr. Freire's principal work—"Doctrine microbienne de la Fièvre jaune." No competent bacteriologist who is acquainted with this monumental piece of pseudo-scientific work attaches any importance to Dr. Freire's alleged discovery. The book itself furnishes ample evidence of the imperfection of his methods of research, and of his numerous errors of observation and of inference.

The *cryptococcus xanthogenicus*, as described in this work, differs essentially from any micro-organism known to bacteriologists in its mode of development, in the variety of forms and colors which it is said to present, and in its biological characters. But the micro-organism which Dr. Freire presented to me as his yellow-fever microbe did not correspond with the descriptions which he had given in his published works. It was a simple micrococcus, which forms a milk-white mass upon the surface of agar-agar, and liquefies gelatine rather slowly, without forming pigment of any kind.

This micrococcus was isolated by the plate method from Dr. Freire's impure bouillon cultures, after his arrival in Paris, by Dr. Paul Gibier, as I have been informed by Dr. Gibier himself. The culture given me was from an agar-agar tube which Dr. Freire brought with him from Dr. Gibier's laboratory in Paris.

Dr. Freire asserts that his yellow-fever microbe is present in great number in the blood and tissues of yellow-fever patients. My extended researches justify me in saying most positively that no such micro-organism is to be found in the blood and tissues of yellow-fever patients.

In numerous inoculations in culture media, with blood drawn from the finger of typical cases, in various stages of the disease, made in Havana, in Rio de Janeiro, and in Vera Cruz, I have not encountered it. It was not present in a single instance in my cultures made in Havana, in May and June of the present year, from the blood and tissues of ten typical cases on which I made autopsies at the military hospital in that city. Nor have I been more successtul in finding it, in several cases on which I have made autopsies, since my arrival in Decatur, where the disease is now epidemic.

Again, this micrococcus is readily stained by the aniline colors usually employed by bacteriologists for this purpose, and would be easily demonstrated if present in the tissues; but Dr. Freire did not attempt to make any such demonstration to me during my stay in Rio de Janeiro, and I did not learn that he had any permanent preparations of this kind; none were ever exhibited to me during my frequent visits to his laboratory, nor did he offer me any pathological material from which to make sections myself. But I brought with me from Brazil pathological material from nine cases which had been secured during the epidemic season, and preserved in alcohol by my friend Dr. Aranjo Goes, and soon after my return I received from my friend Dr. D. M. Burgess material from four cases, which at my request he secured for me in Havana during the summer of 1887. Dr. Burgess had previously (1885), at my request, sent me material from two cases.

From this material—chiefly liver and kidney—I had made and stained, *secundum artem*, a large number of thin sections, and had carefully examined them, with a negative result so far as Freire's microbe is concerned, before I reported to the President my conclusion that there is no scientific basis for Dr. Freire's claim that he has discovered the specific cause of yellow fever.

Very respectfully yours,
GEORGE M. STERNBERG,
Major and Surgeon U. S. A.

DECATUR, ALA., October 17, 1888.

IODOFORM IN HÆMOPTYSIS.—Drs. Chauvin and Jorissenne, in treating hæmoptysis, have employed with advantage iodoform at first, with tannin afterward by itself. Pills were given containing iodoform, ¾ gr., and tannin, 1½ gr. Sometimes the hæmoptysis stopped after two of these had been taken. In one severe case of advanced phthisis, as many as five were given *per diem* for three days before the bleeding ceased. In one patient, who had been in the habit of having eight or ten attacks of hæmoptysis in the year, which had been treated by large amounts of ergotine and morphine, three of the iodoform and tannin pills stopped the hæmoptysis four months ago, and there has been no recurrence since. In three cases, recorded in detail, in which the iodoform alone was used, the results were very similar. The authors came to the conclusion that gr. ij. of iodoform *per diem* in three pills was an appropriate dose for moderately severe cases, and that more than eight or nine pills were not required in any case they had to deal with. Their action they consider quicker than that of ergotine, and, therefore, more useful. In all the cases during the past year in which they had given it, there had been no relapse, and, during the treatment, no disturbance of digestion.—*Le Progrès Médical.*

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from October 21 to October 27, 1888.

FORWOOD, WILLIAM H., Major and Surgeon, Fort Snelling, Minn. Leave of absence, for one month, on surgeon's certificate of disability is granted. S. O. 100, Headquarters Department of Dakota, St. Paul, Minn., October 20, 1888.

WOLVERTON, WILLIAM D., Major and Surgeon. Is relieved from duty at Fort D. A. Russell, Wyo. Terr., and will report in person to the commanding officer at Fort Douglas, Utah Ter., for duty at that post. Par. 16, S. O. 248, Headquarters of the Army, A. G. O., Washington, October 24, 1888.

WILLIAMS, JOHN W., Major and Surgeon. S. O. 209, October 4, 1888, Division of the Atlantic, by direction of the Secretary of War leave of absence is extended one month. Par. 14, S. O. 246, A. G. O., October 22, 1888.

CARTER, EDWARD C., Captain and Assistant Surgeon. By direction of the Secretary of War, granted leave of absence for one month, to take effect on the completion of his present duties. Par. 13, S. O. 246, A. G. O., October 22, 1888.

BARTHOLF, JOHN H., Major and Surgeon. Leave of absence granted for one month, on surgeon's certificate of disability. Fort McIntosh, Tex., Headquarters Department of Texas, San Antonio, Tex., October 10, 1888.

BALL, R. R., First Lieutenant and Assistant Surgeon. Leave of absence granted for one month, with permission to apply for an extension of one month. Par. 3, S. O. 129, Headquarters Department of the Missouri, Fort Leavenworth, Kan., October 18, 1888.

BORDEN, WILLIAM C., First Lieutenant and Assistant Surgeon. By direction of the Secretary of War, relieved from duty at San Antonio, Tex., and to report in person to the commanding officer at Fort Ringgold, Tex., for duty at that post. Par. 11, S. O. 247, A. G. O., Washington, October 23, 1888.

BROWN, PAUL R., Captain and Assistant Surgeon. Relieved from duty at Fort Sidney, Neb., and to report in person to the commanding officer at Fort D. A. Russell, Wyo. Ter., for duty at that post. Par. 16, S. O. 248, Headquarters of the Army, A. G. O., Washington, October 24, 1888.

LORING, LEONARD Y., Captain and Assistant Surgeon. Promoted to be Surgeon, with the rank of Major, October 9, 1888, *vice* Meacham deceased.

Official List of Changes in the Medical Corps of the United States Navy for the week ending October 27, 1888.

SMITH, HOWARD, Passed Assistant Surgeon. Detached from the Wabash and granted six months leave of absence, with permission to leave the United States.

AUZAL, E. W., Assistant Surgeon. Ordered for examination preliminary to promotion to Passed Assistant Surgeon.

WIEBER, F. W. F., Assistant Surgeon. Ordered for examination preliminary to promotion to Passed Assistant Surgeon.

AUZAL, E. W., Assistant Surgeon. After examination detached from Naval Academy, and ordered to Navy Yard, New York.

URIE, J. F., Assistant Surgeon. Detached from the Franklin and ordered to coast-survey steamer Gedney.

OWENS, THOMAS, Assistant Surgeon. Detached from coast-survey steamer Gedney, and ordered to coast-survey steamer Blake.

BERRYHILL, F. A., Assistant Surgeon. Detached from coast-survey steamer Blake, and ordered to Naval Academy.

HARRIS, A. N. T., Assistant Surgeon. Detached from Naval Hospital, Mare Island, Cal., and to wait orders.

HALL, JOHN H., Passed Assistant Surgeon. Detached from the Monongahela, and to wait orders.

CRAWFORD, M. H., Passed Assistant Surgeon. Detached from the Vandalia, and ordered to the Monongahela.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 27, 1888:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	43	11
Scarlet fever	122	16
Cerebro-spinal meningitis	1	1
Measles	117	3
Diphtheria	105	23
Small-pox	0	0
Yellow fever	0	0
Cholera	0	0

THE ANÆSTHETIC REVELATION.—Within a few years it has been discovered that sulphuric ether often produces a most singular effect on the mind of the patient or experimenter who has inhaled it, giving rise to what has been called the "Anæsthetic Revelation." Just as the experimenter recovers from the anæsthetic, and before wide-awake consciousness fully returns, he has an intense perception of what seems to him at the time the philosophic secret of existence—the true explanation of the universe. This singular impression, though intense, does not last long, and in spite of the subject's strongest effort to carry the revelation out into wide-awake consciousness, he finds himself unable to do so, but is left full of awe by his strange experience, and wonder at the nearness of the solution which for so many ages has been sought so far afield. The present brief account has been gathered from the literature of the subject, which grows yearly. Mr. Benjamin Paul Blood, of Amsterdam, N. Y., the discoverer of the phenomenon, originally made it known to psychologists in a pamphlet entitled *The Anæsthetic Revelation*, and he has since discussed its philosophical bearings in the *Journal of Speculative Philosophy*, January, 1886. The most scientific account appears in the *Therapeutic Gazette* for August, 1886, where Dr. George E. Shoemaker, of Philadelphia, relates his "Recollections after Ether Inhalations." *Mind* discusses it in vol. iv., p. 345, and vol. vii., p. 206. Dr. Oliver Wendell Holmes mentions the experiment in his "Mechanism of Mind and Morals" (p. 46). A letter from the poet Tennyson concerning his own experience has recently reached the press; and valuable newspaper accounts of the phenomenon may be found in the *Tribune*, September 3, 1886; the *Evening Post*, October 30, 1886, and the *Utica Herald*, September 15, 1886.—*New York Medical Times.*

THE SOCIETY OF GERMAN NATURALISTS AND PHYSICIANS.—The sixty-first meeting of this Society was held in Cologne on September 18 to 23, 1888. The session was opened by an address from the President, Professor Bardenhauer, in which he reviewed the events of the past year, referring to the nation's loss in the death of the two emperors. William II. sent a telegram of greeting and wishes for the success of the meeting, which was received with loyal cheers. Addresses of welcome were also delivered by Herr von Tirchnow, on behalf of the government, Mayor Becker, on behalf of the city of Cologne, Rector Schönfeld, of the Frederick William University in Bonn, and Dr. Graff, for the Association of Physicians in the Rhine provinces. Announcement was then made of the death of Drs. von Langenbeck, Du Barry, and Clausius, and their memory was honored by the members rising from their seats. The report of the Secretary was then submitted, after which the scientific work of the session was begun by the reading of a paper on "Insanity and Crime," by Dr. Binswanger, of Jena. He discussed the physiognomy and shape of the cranium in criminals, and dwelt at length upon the relation of criminal instincts to insanity, and more particularly moral insanity and dementia paralytica. He did not think that an abnormally shaped cranium necessarily pointed to abnormal cerebral development or indicated a morally abnormal man, but thought that a careful study should be made of all the other facts relating to each individual case before any satisfactory conclusion could be formulated. Dr. Lassar, of Berlin, then read a paper entitled, "The Structure of Public Baths." He presented an historical review of the construction of baths by the ancient Greeks and Romans, referred with regret to the scarcity of public baths at the present time, and urged upon his hearers the necessity of having more bathing establishments, admission to which should be placed at such a low figure that all might avail themselves of the advantages there offered. "Prostitution" was the title of a paper by Dr. Wernich, of Cöslin. The paper contained much statistical information concerning the extension of venereal disease among the German people. He said that syphilis increased markedly in Prussia during the past year, while in other parts of Germany no such increase had occurred. The disease was not nearly as prevalent in Germany as in France, where, according to Fournier, it is increasing alarmingly, a large proportion of nurses and midwives being affected by it. Prostitution, he said, cannot be kept entirely under police control, but it should be so controlled as far as was possible. Every physician should constitute himself a police officer, and see to it that his venereal patients did not spread the disease. Professor Waldeyer, of Berlin, read an essay entitled "Women and the Study of Medicine." In the earliest times, he said, women had filled with success many positions ordinarily allotted to men, but no such liberties had been allowed the sex as was given in the French Revolution in 1792, when for the first time women held equal political privileges with men. In 1864 there was one woman studying medicine in Switzerland, and in 1872 the number of female medical students in the Swiss universities was fifty-one. The rank taken by the first students was high, but it had on the average declined as their number increased. Experience, the speaker maintained, has shown that science makes but slight progress in the hands of women, and even obstetrics has attained its present advanced condition only since men entered the field. It has also been shown in laboratory work that women are not so untiring and exact as men, and that they are easily discouraged by slight difficulties. He even made the ungallant assertion that one female student made as much trouble for the laboratory assistant as thirty men. The conclusion of the essay was that woman has her especial field in the family and in society, but that her excursions into the field of science were uncalled for at the present day. Professor Weismann presented a communication on "The Hereditary Transmission of the Results of Injuries." The speaker did not believe that acquired defects could be transmitted to offspring. He reported a number of experiments on white mice, in which a practice was made of cutting off the tails of many successive generations, yet a tailless mouse always gave birth to mice having normal caudal appendages. Different races of men practised various mutilations, from the ear-boring of Europeans to the cramping of the feet of Chinese women; yet these mutilations were not transmitted to the young, but had to be made anew in each generation. A warm invitation was extended to the Society to meet in Stuttgart in 1889, but it was decided to assemble in Heidelberg. The social entertainments were a prominent feature of the meeting, there being a banquet, with covers for about eight hundred, a ball, a soirée at the Zoological Gardens, and numerous private receptions. The number of members present at the meetings of the thirty sections was upward of fifteen hundred.

Hospital Risks in St. Petersburg.—It may be remembered that a medical officer of the St. Petersburg hospitals, Dr. Dreipolkher, was sentenced to banishment to the Arctic regions a few months ago because he had been unable to obtain admission for a poor woman into any of the hospitals, and in consequence of the delay of a few hours she succumbed to the cold. In this case the entire sympathy of the profession was with the unfortunate doctor, who really seems to have done his best and to have been entirely innocent of the charge of negligence brought against him. It was predicted at the time that hospital medical officers would probably find that the public would take advantage of the severity of the court to bully and terrorize over them, so that any man who accepted a position on a hospital staff would have to run some risk, however well he might do his duty, of being prosecuted or in some way maltreated by thoughtless, overexacting, or evil-disposed persons. Something of this kind has recently come to pass. While a hospital medical officer was engaged in examining a patient in the out-patient department a woman forced her way into the consulting-room and loudly demanded instant attention, as she was in great pain. She had a gumboil, it appears. The doctor told her she must really wait a little till her turn should come, when he would attend to her. She then began to cry and make a disturbance and refused to leave the room, so that he was obliged to summon the attendants to show her the door. Nothing more was heard of the case till the evening, when the husband, who as a customs official may be supposed to be a man of some little education, inquired for the doctor who had seen his wife. As soon as he appeared he struck him several blows on the face, asseverating that the doctor's conduct in the morning had made his wife so ill that she had had to have a doctor to see her since. On inquiry being made at the house, the lady was found contentedly sitting at table, the gumboil having broken.

A Poor Showing for Antipyrin.—At a recent meeting of the Académie de Médecine Dr. Ball read a paper by Dr. Oscar Jennings on a case of poisoning by antipyrin. The patient suffered from nodular rheumatism, for which 2.50 grammes of antipyrin were given daily for a week. On the eighth day erythematous spots were observed on the arms, and the patient had an uncomfortable sensation in the eyes. On the following day the face was red and the eyelids swollen. The day after a rash came out all over the body; there was catarrhal conjunctivitis, loss of appetite, and a sensation of internal cold. The pulse was 78. There was singing in the ears. The patient was very weak. A few drops of tincture of belladonna caused these symptoms rapidly to disappear. Dr. Jennings considers that antipyrin should be given with great caution to old people and persons of an impressionable temperament. The symptoms of poisoning can, however, be easily subdued by administering a few drops of tincture of belladonna, or by subcutaneous injections of atropine. M. Germain Sée observed that he had met with many similar cases. The symptoms of poisoning which he had observed were usually due to doses of three or four grammes of antipyrin, given for several consecutive days. Such symptoms were most commonly met with in female patients. Antipyrin should never be given a second time to patients in whom they had been observed. In such cases antifebrin (acetanilide) should be substituted for antipyrin. M. Sée strongly condemned the practice of giving belladonna or injections of atropine to combat the symptoms of poisoning, which will spontaneously disappear in from twenty-four to forty-eight hours if the drug is discontinued, and which cannot be regarded as of a serious nature. M. Dujardin-Beaumetz, who shares this opinion, remarked that, after a prolonged use, antipyrin caused pain in the stomach and dyspeptic symptoms. The adulteration of antipyrin with benzine or other substances was possibly the cause of these symptoms, which had been more frequently observed of late. M. Dujardin-Beaumetz further remarked that subcutaneous injections of antipyrin were painful. Acetanilide caused cyanosis in certain cases. A dose of two grammes a day should never be exceeded. M. Germain Sée had observed the gastric symptoms described by M. Dujardin-Beaumetz, and believed them to be due to the manner in which the antipyrin was prepared. In order to prevent these symptoms, M. Sée employed carbonate of soda or seltzer water. For subcutaneous injections he gave one gramme in four injections. In this way the injections were not painful. M. Ollivier stated that he did not share the belief held by many authors concerning the good effects of antipyrin. He had employed it in the treatment of chorea, and found that, although it modified the affection in certain cases, in others it did no good. Dr. Allen Sturge, of Nice, also sounds a note of warning against the indiscriminate recommendation of antipyrin. A lady liable to migraine was ordered five grains of antipyrin in powder. Five minutes after the first dose the "deadly sickness" previously present seemed to give way, and an "expanding sensation" was felt, rising from the stomach upward. Almost immediately she sneezed violently about twenty times without pause. The face and eyes became deeply suffused; tears began to flow, and quantities of mucus from the nose; the breathing became hard and labored, accompanied by a feeling of suffocation; there was complete inability to lie down. A violent cough shortly came on, and large quantities of mucus were expectorated. At the same time there was very profuse sweating. After these phenomena had lasted for about half an hour, intense itching was felt on the insides of both thighs, and therewith came a thick outcrop of urticaria, which soon extended to the abdomen. There was also a strong coppery taste in the mouth—not continuing but coming on in violent bouts, and an equally strong smell of the same metallic nature, also intermittent. There was loud singing in the ears, which felt intensely congested. The pulse was thick and very full. The symptoms lasted about three-quarters of an hour and then gradually disappeared, some tightness of the chest and running at the nose remaining for four or five hours longer. The sickness accompanying the migraine disappeared completely as soon as the drug had begun to work; the headache also disappeared for a time, but came back slightly about four hours afterward. (*British Medical Journal.*)

Finally, Eloy, in the *Revue Génerale de Clinique et de Thérapeutique* of March 1, 1888, points out that a large number of ailments are frequently produced by it, particularly if given for any length of time. He quotes Guttmann, Falkenheim, Alexander, and others, in support of his statement that nausea, vomiting, and gastro-intestinal disorders may result from its use. Besides these symptoms he records instances where syncope has occurred under its employment, and Bentzeff is quoted as believing that the drug always produces such a tendency. He asserts that, in the opinion of Moncover, Dujardin-Beaumetz, and several others, the secretion of urine is seriously modified, and one of his references is stated to have put it that "antipyrin closes or shuts up the kidneys." Going still further, Eloy calls attention to the case of Dr. Barr, which is recorded in the *Lancet*, in which collapse and death followed the ingestion of from fifteen to thirty grains of antipyrin in two doses. In a case of puerperal fever, antipyrin caused a fall of over two and a half degrees Centigrade, with vomiting and diarrhœa. Rigors now came on, the extremities became lived, and in thirty-two hours the patient died in syncope. At the autopsy the spleen was found contracted, the kidneys were shrunken, and contained infarcts. A large number of instances were also collected, in which antipyrin has apparently, in the minds of the recorders, produced disorders so varied and so different from one another that it is scarcely possible for them all to be produced by the same drug. It appears to us that Eloy is not justified by the facts he cites in reaching the conclusions as to the dangers of the drug which he sets forth. In the case of puerperal fever to which he alludes, nothing occurred which warrants the attributing of the fatal termination to the use of antipyrin, and the post-mortem lesions indeed point to the disease itself as the cause of death, without any aid from the drug. We think it but a fair conclusion that antipyrin is in no sense a dangerous remedy, and that as yet there are no cases in which death can be attributed directly to its use. All untoward symptoms, clearly produced by any drug, should be reported, but at present the tendency seems to exist of reporting any unforeseen turn in a case as the effect of the drug last administered. Undoubtedly the differentiation is at times difficult, as to whether the symptoms are of the illness or the drug, but every disease runs at times such an irregular course that the careful clinician thinks twice before charging a drug with a change which his own foresight or care might have averted, or at least expected.

Potassium Permanganate in Burns and Frost-bites.—Dr. Zyboff has had good results from the use of permanganate of potassium in the treatment of burns and congelations. He keeps the parts constantly wet with a solution of from three-fourths to two grains of permanganate to an ounce of water. If the integument is broken he employs a weaker solution, one-half grain or less to the ounce.

Local Anæsthetics.—At a meeting of the Société de Biologie of Paris, on April 14th, M. Oscar Liebreich read a communication on substances which cause local anæsthesia. Having been led to experiment on a large number of substances, either natural or produced by synthesis, he found that there were a great many more capable of causing local anæsthesia than had been supposed. Some of these substances have an effect on animals but not on man, for many of them act, not by entering the general circulation, but by their direct effect upon the tissues with which they come into contact. With regard to the cornea, it must be remembered that there are two kinds of anæsthesia. M. Liebreich operated by subcutaneous injection of the dorsal region in rabbits and guinea-pigs. For the eye he merely allowed a few drops of the substance in solution to fall on the cornea. Among the substances producing local anæsthesia the principal are hydrochlorate of ammonia and the bromide and sulphate of ammonia; the carbonate and nitrate are without effect. Hydrobromide of sodium acts, whereas the hydrobromide of potassium is without effect. Sulphate of copper is inactive, but iron salts, particularly the sesquioxide, have an anæsthetic action without producing coagulation at the point of introduction. Acetate of lead is anæsthetic, zinc salts are not. Among organic substances, hydroquinone, resorcin, antipyrin, substances belonging to the digitalis group, and serpent venom, in small doses are active. Thallin, alcohol, ether, and glycerine have no action. Essential oils, such as oil of turpentine, hydrate of terebene, eucalyptol, oil of camomile flowers, and a number of others, have a remarkable effect. According to Dr. Liebreich, these substances act by destroying the nerve-ends and by irritating the neighboring parts, causing what has been called "painful anæsthesia." Some substances, such as cocaine, do not cause painful anæsthesia and are followed by contraction of the vessels, whereas, substances that cause painful anæsthesia lead, on the contrary, to vascular dilatation. Substances causing painful anæsthesia have a caustic action, particularly hydroquinone. This anæsthetic and caustic action is also observed in distilled water. In general a very great number of substances produce local anæsthesia, but in their application to man it is necessary to examine first whether they act as caustics, producing painful anæsthesia.—*Brit. Med. Journ.*

Sound Sense Regarding the Therapeutics of Gonorrhœa.—Dr. Mauriac, in a note on the treatment of gonorrhœa, has summarized his conclusions as follows: 1. The abortive treatment is indicated, and has some chance of succeeding in acute gonorrhœa, only during the first hours of its onset. 2. All the attempts to cut short an attack of gonorrhœa during its period of progression, and when it reaches its height, are useless or dangerous; one obtains only delusive cures. 3. The antiseptic practice at once (*d'emblée*), suggested by the microbian theory of gonorrhœa, has till now produced only delusive results. 4. It is indispensable to submit acute gonorrhœa to an antiphlogistic treatment until the almost complete disappearance of the most inflammatory phenomena. It must proceed to the proper stage of maturity before any repressive medication should be had recourse to. 5. This latter gives decisive and durable results only in the involutive phases of the specific catarrh. 6. The agents of repressive medication are copaiba and cubebs internally, the sulphate of zinc in injections. 7. The balsam should be given first; it sometimes, of itself, produces a definitive cure. In the greater number of cases, while continuing its use, astringent injections may be resorted to. 8. The duration of the repressive medication should be short. Should it not soon give the results expected of it, it must be given up and antiphlogistics resorted to. 9. It is by the antiphlogistic medication that the treatment of acute gonorrhœa, imperfectly cured, should be commenced. These cases, which return almost incessantly, are seldom or never subdued in a definitive manner. —Paris correspondent *Journ. of the Am. Med. Assoc.*

The Surgical Treatment of Aortic Aneurism.—At a recent meeting of the Academy of Medicine, Dr. Constantin Paul read a paper on the Treatment of Aneurisms of the Aorta. He does not defend the method that bears the name of Moore, but he believes it to be useful in certain cases to introduce a foreign body into the aneurismal sac. He shows the defects of the electro-puncture, which produces around the needle a deposit of coagulated albumen without adhesion to the parietes of the sac; it is movable, friable, and forms a veritable grain of emboli. The procedure of Constantin Paul consists in the introduction of a certain number of Japanese needles, which are long and extremely fine, so fine that, to make them penetrate the skin, it is necessary to employ a conductor, which keeps them straight. The needles are left in the sac only a few minutes; they produce a slight degree of adhesive inflammation of the aneurismal sac. After a few days the same operation is recommenced, and a new access of inflammation takes place. In a short time the parietes of the sac become thickened, and the needles cannot be introduced into the points where it appeared that the aneurismal sac was about to open. In these special conditions, this form of surgical intervention, always inoffensive when it is practised as indicated by Constantin Paul, renders real service. Dr. Dujardin-Beaumetz thinks that until some absolutely certain method can be found, all surgical procedures in the treatment of aneurisms of the aorta should be abandoned, and particularly that of Moore. More benefit may be expected from the administration of the iodide of potassium, especially when given in beer or black coffee, or even in milk, as it is then better tolerated, the elimination of the iodide rapidly takes place, and the inconveniences of iodism are prevented.—*Lancet.*

The Medical Record

A Weekly Journal of Medicine and Surgery

Vol. 34, No. 19 NEW YORK, NOVEMBER 10, 1888 Whole No. 940

Original Articles.

GENERAL SUMMARY OF CONCLUSIONS FROM A SECOND SERIES OF ONE THOUSAND CONSECUTIVE CASES OF ABDOMINAL SECTION.

By LAWSON TAIT, F.R.C.S., LL.D., Etc.,

PROFESSOR OF GYNÆCOLOGY IN QUEEN'S COLLEGE, BIRMINGHAM; LATE PRESIDENT OF THE BRITISH GYNÆCOLOGICAL SOCIETY; HONORARY CONSULTING SURGEON TO THE BROOKLYN HOSPITAL FOR WOMEN, ETC.

WHEN I had the privilege, some four years ago, of communicating to this Society the results of my first series of a thousand consecutive cases of abdominal section, I said that I did not know whether the general death-rate, 9.3 (the figure ought to have been 9.2, the fractional increase being an error), was high or low, for no such series had up to that time been published, nor have I seen such a series since. I thought the figure must be high, and I expressed my conviction that, if I lived to complete another such series, the death-rate would be very much lower; and it is with no small satisfaction that I can record a diminution from 9.2 in the first series, to 5.3 in the second. I pointed out that as my first series included my early work, which had been so heavily tainted by the mortality of the clamp and other blunders arising from the traditions of the elders, the mere freedom from these alone ought to give me far better results. That this prediction has been completely verified is certain, from the mere fact that my mortality in the treatment of ovarian and parovarian cystoma has fallen from 8.1 to 3.3. But that by no means represents the full gain which I can point out, for in this class of cases I had, in my previous series, a large group of uncompleted operations with a mortality of at least fifty per cent., and these have now practically disappeared. They were cases chiefly of sessile ovarian tumors, and imbedded cysts of the broad ligament, the removal of which I always now complete, and thus at once diminish my mortality, together with that greatest of all opprobria, imperfect work. I am now in a position to say that no cystic tumor of the abdomen exists which cannot be removed, and this is quite as true of solid tumors of a non-malignant character associated with any organs in the abdomen, except the liver and spleen; and I lay far less stress upon my diminished death-rate as evidence of the improvement of my work, than upon the fact that in my second series I have only to plead guilty to six uncompleted operations in a thousand, whereas in my first series the number was thirty—with the same mortality in each, fifty per cent. Even in these six I know now—for post-mortem examinations revealed the fact—that I could have finished the operations in at least two, perhaps three, if I had screwed my courage up to a still harder strain, and I blame myself accordingly. I therefore lay it down as an axiom, that a man who has a large proportion of unfinished operations is a bad surgeon, worse than one with a high mortality. I may here again assert that I never in any way select my cases, or refuse to operate in such as look unfavorable for my statistical results. This diminution of uncompleted operations may, I think, be fairly and entirely put down to increased experience, giving greater readiness of resource, better judgment, and increased manual dexterity, and to some extent the diminution of the death-rate may be credited in the same direction. But I am proud to be able to say that there is certainly another factor which enters largely into this increased success, and that is the fact that the mind of the general profession is now rapidly freeing itself from the shackles of the ancient authorities of abdominal surgery, and is opening itself to the new rules of progress. The most important of these are two: first, that the principles which govern our actions in general surgery must apply in the abdomen; and the second is, that no doubt or difficulty of diagnosis should stand in the way of adopting that means by which the diagnosis is at once made clear, and successful treatment rendered possible by means of abdominal section. In our Birmingham and Midland district these rules have received an almost universal acceptance, and it is only from outside places now that we get cases which are a disgrace to our art. The day has now come for very plain speaking on this subject, for very many reasons, some of which I have repeatedly urged on former occasions, and a few others which are new. Of the former, I may cite one: Do we not invariably urge a woman who comes to us with an abscess of the breast to have it opened without delay? If so, why should we not deal on the same principle with a woman who has an abscess in the pelvis? We might just as well treat the former with a splint as the latter with a pessary, and this kind of nonsense is one I could illustrate afresh every week from my practice.

A rule was introduced by Mr. Spencer Wells, some thirty years ago, and is maintained stoutly yet by his followers, that an ovarian tumor should not be removed as long as the woman can go about. On the contrary, the rule which I have advocated for the last ten years is, that the time for the removal of an ovarian tumor is as soon after the time of its discovery as is possible. What would be thought of us if we told our patients with enchondromata of the thigh, or sarcomata of the jaw, or lipomata of the neck, or aneurism of the femoral, to nurse and treasure their troubles as long as they could go about? What would we say of a physician who, when he discovered an incipient pneumonia, advised his patient to go about as long as he could, and when he could do so no longer, this physician would come in to treat the case? I ask again and again, why the rules of general surgery and medicine should be excluded from abdominal surgery, and I can get no one to whisper an answer; and I show in every series I publish, with increasing emphasis, that early operations mean successful operations, and I am glad to say that nineteen out of twenty of my neighbors agree with me. But what about the others? Let me give two of my most recent experiences on this subject, they both occurred last week.

A gentleman who is very amiable and good, but somewhat careless in his professional work, sent me a woman in the last stage of exhaustion and emaciation, and he sent me a note to the effect that he had been attending her for three months with a lump in her pelvis, that he could not make out what it was, and that therefore he sent her to me. I opened the abdomen, and removed a huge putrid fœtal sac, the result of a ruptured tubal pregnancy—a thing that ought to have been removed when this gentleman first saw her. Of course she had no chance of recovery, and died a few hours after the operation.

Now, this gentleman's conduct cannot be considered a credit to our profession, and I have in all probability sacrificed his friendship forever by frankly telling him so. For twelve weeks he went on physicking this poor wretch, and when he sent her to me she had nothing left to pay for an operation, and was an object of my charity—a subsidiary, but still certainly an element in the case. But worse still, he secured for me a fatal result which I do not deserve; and worst of all—a crime in my eyes for which there is no forgiveness—he secured for surgery a disaster instead of a triumph. I am speaking strongly, gentlemen, but not more so than I feel; for the advancement of our art depends not more on thos ewho practise such a department as this, than on those who are in the position to give us reasonable chances of success, and that success is essential for all of us concerned in dealing with sick people.

A worse case than this, however, is the second, for the gentleman who sinned as I have described, sinned by an act of omission and in ignorance. But the second was a glowing sin of commission, and based upon that assumed certainty of diagnosis which the foolish and inexperienced mostly are guilty of.

My friend and former pupil, Dr. Gowans, of Perth, sent me last week a woman from that city, who brought with her a note dated March 22, 1888, and signed "Skene Keith," to the effect:

"The case is probably sarcomatous. I told the husband that he must not hope for a recovery, and told the patient herself that when the weather got better she should go out and see if she got stronger. She would be better, I think, with a bottle, perhaps a tonic or stomach mixture."

The case seemed to me rather one of large ascitic effusion, due to an ovarian tumor jammed in the pelvis, and probably fixed there by papilloma. As she had been tapped twice, nothing further was to be got in that direction. With a sort of half-hope that I might get the tumor out, I opened the abdomen, and to my disappointment found that the omentum, mesentery, spleen, and liver were all fully infected by advanced growths of papilloma, the centre of origin of which was a small cystic tumor of the right ovary, covered by dendritic masses. The tumor could of course have been removed, and a recovery for a short time would probably have resulted; but no permament good would have been done, and I might have had to record a death which, had it happened, would have been far more fairly credited to Dr. Skene Keith; and therefore I contented myself with an exploratory incision. From the history of the case I think it is perfectly certain that in March there was no papillomatous infection, possibly no papilloma at all. Dr. Keith's diagnosis of sarcoma is merely an illustration of how completely mistaken we all may be—even the youngest. The blunder consists in his not admitting the advisability of adopting the practice of exploring. Dr. Skene Keith has signallized himself by sneering at some people who open the abdomen on all sorts of pretexts, and his father has bewailed the "restless spirit of abdominal surgery which has lately been let loose;" and they both have laid claim to a freedom from errors in diagnosis to which no others have a right. But such a case as this, and it is by no means my first experience, walking in the footsteps of these two conservatives, makes me satisfied in my restlessness. Had this woman's abdomen been opened last March in Edinburgh, as it ought to have been, she would have been another life saved It is far better that we should even open the abdomen a few times unnecessarily, than that we should deliberately limit the powers of our art in this foolish way.

In my former series there were ninety-four simple exploratory incisions. Of these I said that "ninety-four is a large number, but it must be remembered that years ago I advocated exploratory incisions in preference to first tapping, and that I have persistently carried out the practice. They serve the purpose of complete tappings, and as the patients almost uniformly recover, they do no harm at all." The same is true of the present series, and I never tap as a first proceeding, I always explore. In the present series there are only fifty-three of such operations, and this diminution is chiefly, if not entirely, due to the fact that I get the cases earlier than I used to do, so that I arrive at results exactly the opposite of the disaster just narrated in Dr. Skene Keith's case. There are at least thirty cases in this series in which I have removed tumors successfully, and these, had they been delayed as in his case, would have resulted as in that instance; an argument for early operations and for exploratory incisions which is perfectly unanswerable.

Against the fifty-three exploratory incisions there are recorded two deaths, but these two deaths might be eliminated from the table with perfect fairness, for the operation neither delayed death nor accelerated it by one hour.

I have also to repeat what I said before on this subject, that "occasionally the exploration is followed by drainage, and in some of these cases results of the most marvellous kind have followed—the ascitic effusion has not appeared again." and tumors of spleen, liver, and of other kinds, the nature of which was not ascertained, have disappeared, and the patients have been permanently cured.

I am as far off as ever from my explanation of this extraordinary fact, but as it has received abundant confirmation since I first announced it, it is beyond dispute.

The next group of my series is a lot of two hundred and sixty-three cases of operations for chronic inflammatory disease of the uterine appendages, with a mortality of 3.4 per cent., as against a mortality of five per cent. in my first series, a diminution due largely to increased experience. Here, too, the absence of mere exploratory incisions and incomplete operations is very marked, for there is not a single case of incomplete operation to be credited to this group. These operations are far more difficult in every way than removal of tumors of any kind, and the deaths are almost entirely confined to cases of broken down women, the "too late" cases, as Mr. Bryant well designates them. Since my last paper this subject has been thrashed out in numerous discussions, and has even appeared in the law-courts, but the confirmatory verdict of the lay, as well as that of the professional, jury has been in absolute harmony with all I have said on the subject; useless and diseased organs, incurable by ordinary means, must be removed from the pelvis, just as from other approachable parts of the body; even the lungs are no longer sacred to the "restless spirit of modern surgery." The route of my practice is not governed solely by my own wishes and inclinations. It is far more completely influenced by the judgment of my professional brethren; and the fact that, from all parts of the world, these cases have been sent to me in the increased proportion of two hundred and sixty-three in this thousand, to that of two hundred and one in my first series, is a convincing proof that the benefits of this proceeding are being fully recognized. I am not concerned in the present paper with the ultimate results of such cases, but I may mention incidentally that these have been materially augmented, and the period of convalescence shortened, since the discovery by Dr. Arthur Johnstone, of Danville, Ky.—and it is one of my greatest honors to be able to say that he was one of my pupils—that there is a large nerve-trunk entering (or leaving) the cornu of the uterus, in the angle between the round ligament and the tube, which seems to have a powerful agency in the process of menstruation. When this trunk is secured in the ligature close to the uterus, the results of the operation are more speedily effected, and are more complete.

I have just received a very strange pamphlet with a very attractive title, "Electricity *versus* Tait," surely a subject large enough to attract universal attention. Of the manner in which the author speaks of the defendant in this action, I have no reason to complain; in fact, quite the reverse. It is very flattering, and, I hope, altogether true. But when he speaks of the immediate subject, which is really that of chronic inflammatory disease of the uterine appendages, I feel sure that every skilled reader will come but to one conclusion, that the author has never seen the disease which he professes to cure by electricity. I showed the pamphlet to a skilled electrician a few days ago, and his verdict was that its author did not know what electricity was, or anything about it;

yet the following is a quotation from its pages: "In the use of electricity we subdue the local inflammation; promote absorption of hyperplasia and hypertrophy; establish the general health, and produce proper nutrition. In this manner of electrization we have a means brought to bear upon nutrition, local and general, of such pronounced influence that the result is all that could be desired. By it I have been enabled to carry the class of cases instanced above over the apparent limit of repair; observed thickened tubes and adhesions of long standing disappear, which had resisted every means used to overcome them." By such writing as this we are strikingly reminded of Bishop Berkeley and his book on coal-tar water, from which I might reclaim parallel passages. But the famous metaphysician was floored by the concrete example of a sailor's wooden leg. Let our electrolysists try a living limb of flesh. Gonorrhœal inflammations of the uterine appendages are very common, and similar diseases of the large joints are not unknown. They are almost equally intractable. Fortunately, in the case of the joints the recovery can be greatly assisted by rest in splints. But we cannot put the ovaries and Fallopian tubes in splints; we have no means of giving them physiological rest, short of destroying them; therefore they are in a far worse position than the joints I speak of. Asking among my friends who practise general surgery, I find they say with one accord that gonorrhœal inflammation of joints is a most intractable disease, rarely getting well under the most favorable conditions in less than six months, and often extending over years; finally, that a serious proportion of the cases never get well at all, or get well only with stiff, useless joints. Here, then, is Dr. Berkeley's wooden leg. Let us ask our electrolytic friends to take some cases of gonorrhœal elbows and knees, and let us see what they can do. If they cure them, as they say they cure the same disease in the uterine appendages, then we can believe them about the pelvis. But let them remark the contrast; the joints are outside, visible, and easy of observation, whereas the favorite hunting-ground of quackery is an obscure, mysterious mucous canal. One other word about this "Electricity *vs.* Tait," and I am done with the subject. He assumes, like many other critics, that those of us who deal surgically with the abdomen and pelvis are like Mrs. Wemmick, "Here's a church; let's have a wedding!" "Here's a something; let's have an operation!" So far as I am concerned, this is not so. I have always said that the great bulk of cases of inflammatory disease of the uterine appendages get well without operation, though by getting well we do not necessarily mean that they are cured. All I contend for is that the residuum should not be condemned to live on, hopelessly suffering, while there is a *dernier ressort* at our command. When that should be called in is a matter for determination in each particular case, and depends upon conditions which cannot be formulated into laws, varying as they do in importance, even according to the social position of the patient. Electricity may yet prove the means of still further diminishing the number of cases to be submitted to the surgical method, but it does not promise much in the hands of most of those who have taken it up. Ever since the year 1827, which date indicates, so far as I can discover, the first serious application of the electrical current to the treatment of disease, it has been a source of disappointment to the honest, earnest practitioner, with an exceedingly limited area of exception, while it has, on the other hand, yielded an abundant harvest to the pouch of the charlatan.

Naturally enough this brings me to speak of the treatment of myoma, concerning the electrolytic treatment of which much discussion has taken place within the last two years, since Dr. Apostoli made assertions concerning it which startled the surgical world. To form a judgment on such a subject as this there are two methods, both of which must be applied—the first, open, it is true, to much fallacy, and the second still fallacious, but much more trustworthy; but they must both be tried to satisfy a mind that is logical. The first method is that of *à priori* reasoning, and when Dr. Apostoli's assertions were subjected to this process, it was found that there were grave initial objections to his statements. In the first place, there was nothing new about his processes whatever. It is true he had a new nomenclature, but that was all, and in not a single essential detail were his methods new. Years before they had been tried, had failed, and had been found to be dangerous. Then it was remembered that Dr. Apostoli had made precisely similar assertions about the process of involution of the uterus after labor. He had asserted that all the evils of subinvolution might be obviated by the electric current, his proposals had received a fair trial, and had been uniformly condemned. Cognizant of all this, when in Paris, eighteen months ago, I made very extensive inquiries, and I could find no evidence which induced me even to visit Dr. Apostoli's clinic; for merely to see electrodes applied to patients by a man who had had no experience in gynæcology, whohad received most of his training as an army surgeon, could be of no service. I inquired as to what was known to others concerning the ultimate results of patients who had been treated by his methods, and I heard quite enough to make me determine that I should leave this kind of treatment on this side of the channel to others. I had no desire to complicate my work with such difficulties and dangers as I heard of on all sides, and I was perfectly sure that I should, before long, find that there were others ready enough to try them. Speedily we had accounts in the medical journals of visits to Dr. Apostoli. Dr. Burton, of Liverpool, and Dr. Elder, of Nottingham, wrote such papers. I have heard of two fatal cases in Liverpool occurring in the practice of Dr. Grimsdale, and in which the treatment was carried out by Dr. Burton. I wrote to Dr. Grimsdale asking if the statement were correct, but he has not even answered my letter. Dr. Elder has written to me within the last few days with regard to electrolysis: "I am convinced it will not do as much as some of us hoped. In the *majority* of hemorrhagic cases it certainly is an efficient hæmostatic, although the effect is not always permanent. Now and again, in the same class of cases, it signally fails to modify the flow. *Rarely* under its use a tumor disappears, in a larger number of cases it causes marked shrinking, while in some, even with symptomatic improvement, no diminution in size follows. Pain it usually relieves, and in most cases an improvement takes place in the general nutrition. As it evidently will not abolish hysterectomy, I have invented an 'Elder's clamp,' which I hope you will try."

But all that Dr. Elder admits can be secured by easier and safer means, and therefore electrolysis gains no support from his evidence.

My colleague, Dr. Savage, also went to see Dr. Apostoli, and wrote a paper about what he was told he was seeing, but he does not try the methods, at least not in hospital practice; and when, at consultations, I have urged him to do so in what seemed to me suitable cases, he merely shook his head with much gravity, and proceeded to remove the uterine appendages.

In London electrolysis has been much vaunted by a few, but they are notably those who have been unsuccessful in their efforts at abdominal surgery.

I have, therefore, received no more encouragement from the second or empirical method of investigation than I did from *à priori* argument, and I have left electrolysis severely alone. My own negative experience has quite justified this action, for it is as follows: Since May, 1887, there have been fifteen patients who have passed through my hands upon whom the electrolytic treatment has been tried as a substitute for surgical interference. Three of these have died, though I do not know that they have done so as the immediate result of the electrical treatment. Nine others have returned to me for operation, and have all got well. The remaining three are as yet undecided. In addition to these, I have performed hysterectomy on three patients who had just before been subjected to treatment by electrolysis, and I have removed the appendages in four cases which had been similarly treated.[1] I conclude, therefore, that up to the present we are still in want of evidence in favor of Dr. Apostoli's claims in this country, and, if we take a recent record in Germany, we find all that I urged against it on *à priori* grounds completely confirmed. It is published by Dr. Bröse in the *Zeitschrift für geburtsh. und gynäk.*, Bd. xv., Heft I.

CASE I.—The patient was fifty years of age, a multipara, suffering from multiple uterine myomata; uterus twelve centimetres in length; the tumor reached to within two fingers'-width of the umbilicus. She suffered considerable pain and from pressure-symptoms; menstruation regular.

During treatment the pain ceased and the tumor got smaller. After the ninth sitting the tumor reached thirteen centimetres above the symphysis. The patient absented herself for nine months, and came back worse than before. The tumor had grown again, and the uterus measured twelve and one-fourth centimetres.

On using the constant current the symptoms again abated. After eleven sittings the uterus was eleven centimetres long; the patient then left my care.

CASE III.—Patient aged twenty-nine; one child; submucous myoma. The uterus was as large as a four months' pregnancy; there was much dysmenorrhœa and menorrhagia. After one sitting (1½ milliampères), slight pains like labor-pains; second sitting (20 milliampères), strong contractions of the uterus, with labor-pains which lasted for two days continuously till the next sitting. Bloody discharge; pieces of tissue (myoma) were passed; a badly smelling discharge came on; the myoma had necrosed and was being cast out. The constant current was applied twice again; the necrotic mass removed with spoon; the uterus drained. Death, five days later, from septic peritonitis.

CASE IV.—Aged thirty-six; multipara. Uterine myoma; great pain and much dysmenorrhœa. No result after twelve sittings. Hysterectomy was successfully performed.

As a contrast, let me submit a group of 148 cases of removal of the uterine appendages for myoma, with three deaths, giving a mortality percentage of 2.03, as against my 99 cases in the former series, with a mortality of 7. I have already published in detail (*British Medical Journal*, September, 1885) proof of the satisfactory and permanent results obtained from this operation, and have only, in addition, to say that these are maintained. I have, in the two series, to include 247 cases, with 10 deaths. Of the 237 cases I know that 3 have since died of cancer, and that 3 have had hysterectomy performed, owing to the subsequent growth of the tumor, and I know of no other failures.

The next group is that of 88 hysterectomies, with a mortality of 11.3 per cent.; a striking contrast to my previous series of 54 cases, with a mortality of 35.7, a result so distressing that I utterly condemned the operation. But, as Dr. Elder says, we are driven to it, no matter what Dr. Keith says, and if Dr. Keith had not refused to let me see him do the operation, my mortality in this series would have been less than it is now, for he had a method of operating which I did not know, and the knowledge of which at once reduced my mortality enormously. The point was a very simple one. He tied the broad ligaments separately, and stripped them off the uterus. He does not seem to have appreciated the reason of the success of this method, but the explanation is very simple. It prevents occlusion of the rectum by taking off strain. The fact that I have gone so far as to have 31 consecutive recoveries from hysterectomy satisfies me that before long I shall bring its mortality down to something approaching that of ovariotomy.

I have already said, in previous writings, all that need be said concerning such operations as cholecystotomy, nephrectomy, nephrotomy, opening and draining pelvic abscesses, and operations for tubal pregnancy. I have nothing to alter, and nothing to add.

For the relief of intestinal obstruction I still prefer to perform enterotomy rather than make prolonged searches for the seat of obstruction. I have put a group of these cases together, but they have so many divergent features that no efficient conclusion can be derived from mere statistical display. I propose to make this subject the basis of a special paper to the Midland Medical Society during the ensuing session.

Of suppurating peritonitis treated by abdominal section, washing out, and draining I have to speak in terms of unqualified satisfaction. I have lumped together all the cases, save those that were puerperal, in the same group, for it really is impossible to draw hard and fast lines between the acute cases and the chronic. I have operated, in this series, on 26 cases, and have saved 22. I say saved, advisedly, for without the opening of the peritoneal abscess they must all have died. The mortality is 15.3 per cent., and in my first series I had 9 cases, with a mortality of 22.2 per cent. Here again I must plead with my brethren for assistance, and urge that cases of purulent effusion in the peritoneum should be treated by early and efficient drainage, just as purulent effusion in the pleura is dealt with.

Of puerperal peritonitis I have to speak still with bated breath. I have operated four times and had only one recovery. But I nearly had two others, and I believe, if I had obtained twelve hours' start in these two cases, the mortality of my little group would have been twenty-five instead of seventy-five per cent.

In London this operation has been received with much favor and has had very fair success. In a communication on the subject, Mr. Treves expresses a view which seems to imply that in my practice the operation arose in a sort of blundering way, in a case which I did not know what I was about; and subsequent writers are therefore disposed to give Mr. Treves the credit of introducing this practice. Mr. Treves is quite mistaken about my introduction of the operation, which took place in a case sent to me by Dr. Arthur Underhill, in 1879. Dr. Underhill had diagnosed the case completely, and I quite concurred in his view of it; I therefore opened that patient's abdomen, not only knowing quite well what I was about, but with the full intention of relieving my patient, and I was successful. The operation was performed on October 30, 1879.

Puerperal peritonitis—puerperal fever, as it is practically called—is a deadly disease. The recoveries from it are quite fractional. The argument, therefore, for attempting to save such cases by opening or cleansing is surely a strong one, but it must be fairly tried; that is, it must not be left merely to close the scene with. I am strongly disposed to think that in severe cases of puerperal inflammatory mischief the chief trouble is in the womb itself, and I am inclined to think removal of the organ in its inflamed condition may be requisite. In any case, the disease is so hopeless when left alone that any kind of effort seems legitimate.

---

[1] The only case in which I have seen pronounced benefit derived from the treatment by electrolysis is one which occurred at the hands of Dr. Apostoli himself. It was a case of subinvolution and chronic metritis, with the invariable retroversion of the uterus, accompanied by chronic catarrh of the endometrium. This lady went over to Paris and had, according to her own account, thirty-one applications of the electric current, several of which were conducted under an anæsthetic. Of course she does not know exactly what was done, but she tells me that the treatment was so severe that nothing would induce her to undergo it again. It occupied five months, and cost a very great deal of money. Now such a case as this could be, and certainly in my practice is, invariably cured by the simple process of dilating and curetting the uterine cavity, and applying Paquelin's cautery freely to the inside. This proceeding is absolutely devoid of risk; nothing in the least approaching anxiety has ever been experienced in an enormous number of cases I have successfully treated. The pain is infinitesimal, and only one sitting is required. The cost is a mere bagatelle. I do not see, therefore, that the electrolytic treatment can be accounted in any way an advance upon the treatment by curette and actual cautery; in fact, it is entirely the contrary.

One small group of cases remains for discussion, as it is full of interest. I mean those in which the pregnant uterus was amputated because it was impossible to remove the child by the natural passages. In my life I have three times performed the old Cæsarean section, and the mother died in every case. In a fourth case, seven years ago, I did exactly what Sänger claims as a new operation, and I removed the appendages to prevent future impregnation, but the patient died. I put all these deaths down to the fatal influence of the "puerperal condition," but it is clear that that explanation is nonsense, for I have now done four operations on the principle laid down by Professor Porro, and all the mothers have recovered, and the children have all lived. The operation I perform is certainly not Porro's operation, for I have altered nearly every detail, but the discovery of the new principle, that of removing the uterus to save the mother from the fatal effects of suppurative metritis and the possibility of having the same trouble over again, is the credit of my friend, Professor Porro. I prefer to give the operation the name of no particular person, because men's names attached to operations are always productive of misunderstandings, quarrels, and confusion. I indicate the principle by calling it "amputation of the pregnant uterus," every word of this term being fact and not theory.

This operation, I venture to predict, will revolutionize the obstetric art, and in two years we shall hear no more of craniotomy and eviscerations, for this new method will save more lives than these proceedings do, and it is far easier of performance. It is the easiest operation in abdominal surgery, and every country practitioner ought to be able and always prepared to do it.

No special instruments are required, nothing but a knife, some artery-forceps, a piece of rubber drainage-tube, two or three knitting-needles, and a little perchloride of iron.

My method of operating is to make an incision through the middle line, large enough to admit my hand, and then I pass a piece of rubber drainage-tube (without any holes in it) as a loop over the fundus uteri and bring it down so as to encircle the cervix, taking care that it does not include a loop of intestine. I then make a single hitch and draw it tight round the cervix, so as to completely stop the circulation. I give the ends of the tube to an assistant, who keeps them well on the strain so as to prevent the loose knot from slipping, the reason for this being that, should there be any bleeding and any necessity for further constriction, I could secure this in a moment without undoing any knot; and the simplicity of this method greatly commends it. I then make a small opening in the uterus, and enlarge it by tearing with my two fore-fingers, seize the child by a foot and remove it. I then remove the placenta, and by that time the uterus has completely contracted and is easily drawn through the wound in the abdominal wall. The constricting tube will now probably require to be tightened, and the second hitch of the knot may be put on at the same time, and the work is practically done. Stuff a few sponges in the wound to keep the cavity clear of blood, and pass the knitting-needles through the flattened tube and through the cervix, and in this simple way a clamp of the most efficient kind is at once made; the uterus is removed about three-fourths of an inch above the rubber tube. The usual stitches are put in, the wound closed round the stump, which, of course, is brought to the lower part of the opening, and then the stump is dressed with perchloride of iron, in the usual way. The operation takes far less time to perform than it takes to describe, and as there is hardly any possibility of complications, it is one of the simplest operations that can be undertaken, and must always be pretty much the same; for this reason no one need ever be in any fear about undertaking it, for in the absence of variation in the difficulties to be encountered, it differs entirely from any other operation in abdominal surgery.

If performed before the patient has been mauled about by ineffectual attempts to deliver, its mortality will be no greater than that of ovariotomy, and the arguments in its favor against all alternative proceedings are, first, that it cannot be more dangerous to the mother than most of these are; that it saves the life of the child; that it prevents the unfortunate mother from again being placed in a similar condition; and it certainly has the great advantage over alternative proceedings having a similar object, that its great simplicity, as contrasted, for instance, with operations proposed by Thomas, Müller, and Sänger, will make it possible for the country doctor less experienced in surgery to perform it without hesitation. These complicated and difficult proceedings may have their advantages, though I confess I do not see them; but they will be left for the hands of experienced specialists. The operation I have described will be the operation of emergency, where only the resources of general practice are at hand.

ANTIPYRIN FOR THE RELIEF OF LABOR PAINS.—A German practitioner has lately stated that he has succeeded in minimizing, or even preventing entirely, the pains of childbirth, by the administration of enemata of antipyrin. In the case of one woman, with her first child, who had been in great agony for upward of twenty hours, after a single injection per anum of about half a drachm of antipyrin to a few ounces of water, the pain ceased almost immediately as if by magic, although the uterine contractions continued without alteration or diminution, and the accouchement proceeded in an entirely satisfactory manner. He also records cases where one or two antipyrin enemata rendered premature labor absolutely painless. Another authority, Dr. Layel, of Marseilles, has met with the like success, in similar cases, by the employment of this drug. Equally satisfactory results have attended the administration of antipyrin in this manner in England, and consequently it is likely to be extensively employed. Thirty to thirty-five grains (two grams) is the quantity recommended for each enema, and even in very severe cases a second or a third injection, after a short interval, suffice to relieve the patient from all her pain.—Cor. *Journal of the American Medical Association.*

SOME SUGGESTIONS CONCERNING THE PREVENTION OF CHRONIC JOINT DISEASE IN CHILDREN.[1]

By LEROY W. HUBBARD, A.M., M.D.,

NEW YORK.

WHOEVER carefully studies the history of medical progress will find that during the past century, and especially the latter part of it, the greatest advances have been made in the departments of surgery and preventive medicine.

Why is it that the results of surgical operations are so much better than they were twenty-five years ago? Certainly we have no more skilful operators to-day than formerly, nor is the present generation more rugged and better able to endure the shock and strain of operations than the preceding ones. No! it is simply because we have found out the ordinary causes of danger, and the means by which they may be rendered harmless.

In the department of medicine, the search for the primal cause of disease has interested a large number of scientific investigators, and so successful have the results of their labors been, that we now know positively, or with great probability, the cause of all the acute infectious diseases; and, as a consequence, the means for the destruction of these causes, or for rendering them innocuous.

No one can say that the present generation possesses more physical vigor than those which have preceded it; nor are the habits and mode of life of the people to-day calculated to prolong existence; yet it has been calculated that the average age of a generation has been raised from thirty to thirty-six years.

In spite of the ignorance of the masses, and of their inability to appreciate the necessity of sanitary laws, the persistent efforts of some of the more enlightened and civilized governments have had their effect, and the terrible epidemics of disease which once swept over a country, decimating the inhabitants, have become things of the past, and their history reads like the tales of goblins and giants which frighten children in the dark.

It has seemed to me, in looking over the history of this triumphal march of progress, that the department in which we are especially interested has not kept in the foremost rank, but has fallen somewhat in the rear in this respect.

No one can question the great progress which has been made in the treatment of chronic joint diseases and deformities after they have appeared, and the results are brilliant triumphs, due to the skilful application of apparatus or manipulation of the knife. Nowhere have these results been more successful than in this country, and the orthopædic surgeons of the United States undoubtedly have no superiors in the treatment of the cases which come under their charge.

We find the literature, in this country, on the subject full of suggestions in regard to treatment; descriptions of new forms of apparatus which are expected to work wonderful cures; statistics of results, often biased by the peculiar hobby of their author or compiler; while the pathology and etiology of these diseases have either been neglected or treated in a superficial manner. As exceptions to this general statement, I must mention the writings of Drs. Shaffer, Gibney, and R. J. Hall, who have added materially to our knowledge of the etiology and pathology of chronic joint lesions as the result of their careful and scientific investigations. Dr. Samuel Ketel, also, in a paper recently read before this society, called attention to the insidious nature of scoliosis, and advised careful observation of young children with a view to the prevention of the trouble.

But these contributions are small when compared to the reams of literature on the subject, and it has occurred to me, therefore, that it might be well at this time to consider the possibility of preventing these chronic joint lesions, which have been and are now so common among children, and whose destructive progress we are so often unable to check, though we may see our patients very early in the history of the disease. While we may do much to mitigate their suffering, still the best results attainable are often impaired function or permanent disability.

In my remarks I shall confine myself to a consideration of only those cases of chronic joint trouble which are commonly known as *fungoid.* I am aware that there are other forms of joint lesions, such as the syphilitic and rheumatic, but they are so uncommon among children that I think they can be left out of consideration.

In order to arrive at a rational method for the prevention of any disease, it is necessary to understand its pathology and etiology.

The pathology of chronic joint lesions, at least in their gross appearances, has been often described and pretty generally agreed upon, but a fierce battle has been waged over the question of etiology.

The opposing factions may be said to have divided themselves into the traumatist and non-traumatist. The one has claimed that in the large proportion of cases of vertebral caries, morbus coxarius, knee-joint disease, etc., a history of traumatism can be obtained which has a direct causal relation to the lesion; also, that the disease frequently occurs in a healthy, robust child whose family history is good, and who has presented previously no evidence of a hereditary or acquired diathesis favorable to the production of a joint lesion.

The other side claim, just as strongly, that a peculiar diathesis or constitutional taint is always necessary. They base their claim upon the undoubted facts that in many, and perhaps the majority, of cases, there is a definite family history of some constitutional disease, frequently tuberculosis; that in a large proportion of cases no injury is assigned as a cause by the parents; and that, when an injury is assigned as a cause, it is frequently trivial, or occurred several weeks previous to the first appearance of the symptoms, the child in the meanwhile being perfectly well.

As is usual in such cases, both sides are partly right and partly wrong; and it will be my endeavor to show, if possible, how both theories may harmonize.

In the first place it is necessary to state two propositions which must be accepted at the outset:

First. Tuberculosis is produced or caused by the direct action of the tubercle bacillus.

Secondly. Chronic joint lesions of the fungoid variety are tubercular.

The first of these propositions needs scarcely comment or proof.

Ever since Koch, in 1881, announced his discovery, after months spent in patient and careful work, and after each elaborate experiment had been verified again and again, the subject has aroused the enthusiasm of all workers in bacteriological investigation. Although his theory was for some time opposed and his facts disputed by the more ignorant and careless experimenters, I think I am safe in saying that to-day there is not a man, whose opinion is worth considering, who does not accept Koch's conclusions.

Rokitansky, justly called the father of modern pathology, as early as 1850 advanced the theory of the tubercular origin of chronic joint disease, but his opinion was not accepted, and for several years nothing was heard of it. Later, Volkman mentioned that it might occur, but thought it rare. Köster, Friedlander, Schüppel, and others followed up the work, but no satisfactory result was obtained, owing to the fact that scarcely any two observers were agreed as to the macroscopical or microscopical appearance of tubercle. But after the discovery of the tubercle bacillus, the investigations of Kœnig, Rosenbach, Dr. R. J. Hall, of this city, and others, have proved beyond doubt that chronic joint lesions are tubercular.

From these premises we can draw but one conclusion viz., that chronic joint disease is due directly to the presence and action of the tubercle bacillus; in fact, that *it*, and it *alone*, is the active and primal cause.

---

[1] Read before the Orthopædic Section of the Academy of Medicine, April 20, 1888.

The bacilli gain entrance to the system in one of four ways. In a certain very small proportion of cases they are transmitted directly to the fœtus by one or both parents, who may be suffering at the time of conception from active tuberculosis.

Secondly. The bacilli may be directly inoculated. This is proven by the case of the Hebrew rabbi suffering from laryngeal phthisis, who inoculated twelve children whom he circumcised; also by the case of a servant of one of the professors in the University at Vienna who was ill from phthisis pulmonalis. During the last few weeks of his illness his sputa contained almost pure cultures of the tubercle bacilli. The servant, who was a robust, healthy girl, with no hereditary taint, accidentally cut her finger by the breaking of the receptacle containing sputum. The original wound healed readily, but in a few weeks a local tuberculosis developed upon the tendon of the finger and the glands of the arm, which showed numerous bacilli.

By far the most common modes of infection are by inhalation through the lungs, and by the alimentary canal.

On the other hand, it may be asked, does the presence of a tubercle bacillus in the system necessitate the formation of a tuberculous lesion? By no means, for if it did, few of us would escape, surrounded as we are by continual sources of infection.

The organism must find a soil suited to its growth, or it will not develop. There is a constant struggle between the vitality of the bacillus and the vitality of the living cell.

It is only upon this theory that we can rationally explain the course of any one of the infectious diseases; why one person is susceptible and another not; why one has a severe attack and another a mild one; or why a slight exposure will produce the disease in one individual, while another requires a long-continued and strong exposure.

A case occurring in my own practice is in point. A young lady, who in childhood did not contract measles, was exposed to them frequently, and, in her capacity as teacher in a boarding-school, had often taken care of pupils ill with the disease without contracting it. This year, though in apparently better health than for several years past, she contracted the complaint from slight exposure.

Dr. Daremberg, in his article upon the "Contagiousness of Tuberculosis,"[1] says, "the degree of contagion is controlled by the individual characteristics in those prepared beforehand for infection by hereditary or acquired vices of nutrition."

Moreover, pathologists inform us that they frequently find, in the bodies of persons who have died of other diseases, spots of local tuberculosis which have produced no symptoms and have not been recognized during life.

Daremberg[2] thinks that a local tuberculosis is produced by an attenuated virus, or by a microbe which has undergone some change that renders it less virulent.

Cornil thinks the same, and says that the local tuberculosis has a tendency to remain so, but the microbes may become changed by favoring conditions and produce general infection. These statements are borne out by clinical experience, for we all know how few patients with chronic joint lesions, comparatively, die from general tuberculosis or infection of internal organs; and when it does occur, the infection is generally preceded by an exacerbation of the local trouble.

Dr. Sayre, in his work upon "Diseases of the Joints," refers to the familiar robust, ruddy-faced old man with a short leg from hip disease, as a proof that the disease is not dependent upon a diathesis. The only fact which such a case proves is that the lesion was a local one and did not become general.

Having thus determined upon an active or exciting cause for the lesions in question, let us consider the predisposing causes or the conditions which favor the growth and development of the bacillus. These may be divided into general and local.

Under the first I will place at the head heredity. By this I mean, not a direct transmission of the tubercle bacilli, except, perhaps, in very rare instances, but, as Daremberg expresses it, "the inheritance of vices of nutrition which produced the disease in ancestors.

Gibney, in his article, "The Strumous Element in Joint Disease," states that he found that, of 185 cases of Pott's disease, 76¼ per cent. of the parents had suffered from some hereditary disease, and of 272 cases of hip disease, 60¼ per cent. Of 568 cases of Pott's disease which came to the New York Orthopædic Dispensary, from 1870 to 1878, thirty per cent. gave a direct tubercular history, and of 463 cases of hip disease, twenty-five per cent. These histories were all obtained from the statements of parents, and probably the percentage is under rather than over the actual facts. We cannot, therefore, avoid considering heredity as a strong predisposing cause.

Next, I will mention environment, hygiene, nutrition, etc.

The experiments of Dr. Trudeau, reported in the *American Journal of the Medical Sciences* for July, 1887, are strong evidence on this point.

Experiment I.—Five rabbits were inoculated in the right lung and left side of the neck with five minims of a solution containing a pure culture of the tubercle bacillus. They were then placed in a box in a dark cellar, deprived of light, fresh air, and exercise, and the supply of food was limited.

Experiment II.—Five healthy rabbits were placed in a pit ten feet deep, within a box having sides but no top. The only access to the pit was by a small trap in the roof. through which food was introduced once a day, the quantity being limited to one small potato for each rabbit. The bottom of the pit was so damp that the animals were always wet.

Experiment III.—Five healthy rabbits were inoculated as those in Experiment I., and turned loose upon an island where they had the best possible conditions of light, air, food, etc.

Results. Experiment I.—Four of the rabbits died within three months, and all presented tubercles which gave pure cultures of the bacilli. The fifth was killed at the end of four months and showed well-marked tubercular lesions.

Experiment II.—All the animals were alive at the end of four months, and though emaciated, were lively. When killed, no tubercular deposits were found.

Experiment III.—One of these rabbits died at the end of one month and showed some tubercular lesions. The other four were killed at the end of four months, and found to be perfectly healthy.

Of the animals which were directly inoculated and placed in bad hygienic surroundings, four died and the fifth was infected.

Those which had simply bad hygienic conditions did not develop the disease, and of those inoculated but placed under the best conditions for resisting the bacilli, only one succumbed.

These experiments speak for themselves, and demonstrate that tuberculosis is not developed from bad hygiene alone, and also that the surroundings are an important element in the development of the disease when the bacilli are present.

Anything which produces a lowered vitality of a joint, or epiphysis, may be considered as a local predisposing cause of a chronic lesion. Without doubt, the most common cause under this head is traumatism.

Pathologists generally agree, and chemical experience confirms the opinion, that these lesions usually begin in the bone; either in the epiphysis or at its junction with the diaphysis. Now, we know that this portion of bone, especially in children, is very delicate in structure and extremely vascular. A slight disturbance of the arrangement of the bone-cells might easily produce such changes in the circulation as to seriously affect the nutrition of the part.

---

[1] Bulletin de l'Académie, 1884.

[2] Loc. cit.

Max Schüller says, in the *Weekly Gazette*, February 23, 1883: "A point of traumatism is prepared to receive a microbe which, under other circumstances, would circulate through the system without producing infection."

Some experiments upon animals may be given in evidence.

Schüller, of Greifswald, in 1880, injected into the lungs of some dogs tubercular sputa, or an emulsion of cheesy material; other dogs he infected through a wound in the trachea; and still others were confined in a small room, into which was constantly thrown a spray containing tubercular material. Upon all of these dogs he inflicted slight traumatisms of the joints by wrenching them or pounding them with a mallet, lightly but often. In every one a chronic fungoid arthritis was produced, while the same traumatisms inflicted upon other dogs, not infected with tuberculous material, produced only serous effusions which quickly subsided.

Cornil inoculated with dried sputum a rabbit in which the sciatic nerve had previously been cut. Two months after there was a localized fungous arthritis of the knee-joint, and a tubercular lesion of the tibia, both of which contained bacilli.

The traumatism may be a single severe injury to the joint or epiphysis, or, what is probably more common, a slight traumatism often repeated.

It is well known to everyone that children in their sports are continually receiving more or less serious injuries of the joints. Sometimes these injuries cause considerable suffering at the time, but the acuteness of the pain soon wears off. The child then uses the joint, enduring the slight pain without complaint, for fear of punishment or restraint from joining in its accustomed plays.

Many of the sports indulged in by children, of which the familiar skipping-rope is a good example, are calculated, by producing a slight but often repeated traumatism upon the joints, to set up a low grade of inflammation, constituting a favorable soil for the growth of a tubercle bacillus, should it be present. If you have observed a young child descending a flight of stairs, I think you cannot have failed to notice the amount of traumatism inflicted upon the knees and hips. Instead of descending one foot after the other, with the limbs partly flexed, so that the force of concussion is distributed along several curves, one leg is kept continually in advance, and the whole weight of the body is dropped, as it were, from one step to the other, the limb being held stiff and the joints receiving the direct force of concussion.

The argument that very severe traumatisms of joints frequently do not produce chronic lesions of those joints, proves nothing except that the exciting cause was not present, or did not find a suitable soil for its growth. In fact, a chronic lesion is less liable to follow an acute and severe injury than a slight or often repeated one, for the well-marked symptoms produced call for immediate treatment. The joint receives absolute rest for a considerable period, the acute inflammation subsides, and the normal conditions of the joint are restored.

The argument that, as a rule, when a history of traumatism is obtained, we find the injury to have occurred several weeks or months prior to the first appearance of the symptoms, falls to the ground, for that is just what we should expect. The tubercle bacillus is very slow in its growth, and if only a few microbes are present in the beginning, it will be some time before they will produce sufficient change in the bone or joint to present active symptoms.

We have seen, also, how the disease may be brought about through trophic changes in the joint, as illustrated by Cornil's experiment after division of the sciatic nerve. Clinically, it has been observed that chronic joint lesions frequently follow the acute exanthematous diseases. It is believed by many observers, that there is a great increase in the vascularity of the epiphysis of the long bones during these diseases, and an actual growth has been observed in some cases during the few weeks in which the patient is confined to the bed. It is possible that such changes are produced in the articular extremities as to afford a suitable soil for the lodgment and growth of the tubercle bacillus.

Based upon the foregoing facts in regard to the pathology and etiology of chronic joint lesions, I offer the following suggestions for their prevention:

1. A careful inquiry by the surgeon into the hereditary history of each family which he may have charge of; and if a well-marked history of hereditary disease, especially tuberculosis, is found, a warning should be given to the parents of the dangers to which the children are exposed.

2. Instruction in regard to hygiene, diet, etc., with the endeavor to keep the nutrition of the chidren up to the highest point until they have passed the period at which they are most liable to contract a joint lesion, viz., the period of puberty.

3. When tuberculosis is present in a family, either as phthisis pulmonalis, or a joint lesion with an abscess, all sputa or discharges should be destroyed or disinfected; and healthy children should be brought as little as possible in contact with the sick. In this way the risk of direct contagion may be reduced to a minimum.

4. Instruction should be given in regard to the importance of any traumatism of a joint or the parts near it, however slight it may be. After such an injury, absolute rest of the joint should be insisted upon until all evidence of inflammation has subsided and the function of the part is perfectly restored.

5. The prohibition of all sports or exercises which bring repeated traumatism upon one joint. Young children should not be allowed to go up and down stairs frequently.

6. After one of the acute exanthematous fevers, a considerable period should elapse before active exercise, such as running, jumping, or long walks, is allowed.

CARBO-OXYGEN IN CONSUMPTION AND OTHER FORMS OF WASTING DISEASE.

By HOLMAN S. HUMPHREY, M.D.,

WHITEWATER, WIS.

In the April number of the *Medical Age* I published an article under the above title in which I described my method of using predigested carbonaceous principles for rectal alimentation, followed by injections of pure oxygen gas (for injection the gas should not be diluted). As a carbonaceous food for these injections, I prefer cod-liver oil properly emulsified. Yolk of eggs, beaten with cream, pancreatin, and soda, makes an excellent emulsion for this purpose, as does also the clear oil obtained from breakfast bacon similarly emulsified; whatever carbon principle is used, the object is to get fatty matter furnished to the system without disturbing the upper digestive tract.

I find, in cases of extreme debility of the stomach, liver, and pancreas, in which fatty matters can neither be emulsified nor assimilated, and in which such foods give rise to disgust and loathing, that it becomes necessary to use such foods in some other way. I have in the past tried to furnish such material by fatty inunction, by filling the vagina with such foods and by resorting to the late Dr. Fothergill's method of "body-guarding" emulsified oil through the stomach with soda bicarb.; but in every case I met with disappointment. Too often, in such cases, the skin is dead as parchment, the vagina lifeless, and then, besides, male patients have no vagina—a fact which some recent writers seem to have overlooked—and body-guarding emulsions through the stomach is necessarily a failure where the disgusted nose and palate turn up and retch at each dose. All these efforts fail because they do not reach the purpose aimed at—absorption into the blood and oxidation among the tissues of the body; for carbon in the human system, as elsewhere, is only potential energy until it meets with oxygen, and as these are the great force-producing elements of life, it occurred to me that by furnishing these to the victim of wasting disease we could pick up and push forward the flagging energies of the body until it could assimilate other foods. In order to do this we must utilize the shortest and most accessible route to the blood, and one which shall call for the smallest modicum of vegetative nerve-force in attaining that end. In such cases I found the lower bowel, with its extensive secreting surface, to be the road to success; its lymphatics as ready to absorb digested oil and its portal venules as ready to absorb oxygen-gas as similar vessels in the upper intestine. I reject albuminoid foods as completely as possible until I have overcome the extreme debility of the liver, as all digested peptones must pass through that organ before they are finally metabolized; and this is precisely what I wish to avoid, because in such liver conditions as mentioned, although nitrogen elements may be presented to its cell-structure thoroughly digested, yet it is powerless to split up such materials—converting them into water, urea, and carbonic acid, but instead, compounds of less complex structure are made, as bile acids, uric acid, etc. Thus, in our effort to feed our patient, we poison him instead. The same is true if we fill the alimentary tract in the usual way with peptonoid foods, because such food must pass through the liver, it matters not at which end of the line introduced; and when that organ is helplessly diseased, by such feeding we simply give our patient a stone instead of bread.

Filling the alimentary canal with food is not always feeding the body; indeed, so far as immediate benefit is concerned, food might as well be held in the hand as in the stomach, for it is only after digested principles have passed the epithelial frontier of the intestine that they become food in the true sense of the word. True, in the healthy man the mere presence of food in the stomach gives a sense of well-being, but in the wasted invalid, whose entire system has for months been subjected to the blighting influence of malnutrition, the presence of food too often gives pain instead of pleasure.

In every case of consumption and other forms of wasting disease there is present from the first inception of the malady a marked inability to appropriate a normal quantity of oxygen by respiration; this may be owing to defective structure, confinement in-doors, nervous debility, catarrhal disease of the mucous membrane of the air-passages, in which the ciliated epithelium are impaired in activity and the smaller bronchi loaded with filth. Let the cause be what it may, so soon as a normal quantity of oxygen fails to reach the blood and tissues the digestive and assimilative powers fail, followed by impaired circulation of blood and malnutrition. The earliest defect in digestion is in the direction of fatty matter, for the reason that sufficient oxygen is not present to utilize these foods, as two hundred and ninety-five parts of oxygen are required for every one hundred parts of fat, and failure to get oxygen means want of power to digest fatty food, and a wasting of tissue must follow, with all its attendant evils. This is not alone true of carbonaceous foods, but of all foods, as the quantity of oxygen present determines the capacity to digest any and every kind of food known, and the "stuffing plan" of feeding the sick beyond their capacity to oxidize is a slow but certain method of poisoning them. Alimentary substance is food when the forces stored therein are given to the body by oxidation, and not otherwise.

Dr. Samuel S. Wallian has well said: "The first idea in the treatment of wasting disease is to renew tissue." Desirable, however, as this is, unless fatty matter can be supplied to the extent of running the entire processes of vegetative life so far as heat (force) is concerned, tissue renewal is absolutely out of the question, as this can only take place when there is a surplus of both pabulum and force above the wants of the actual running power of life.

In consumption it is only after fats are absorbed and their supply inadequate for their deposits that muscular waste is possible, and when the powers of the system are so far reduced that carbonaceous foods are no longer assimilated normal histogenesis is impossible, and when repair of tissue is forced by any process using abnormal materials for repair, such tissue cannot live, and a breakdown is sure to come. Hence my first aim is not so much to renew tissue-elements as to preserve what the patient already has, and stop muscular waste by supplying heat-producing materials for oxidation; for, so long as we can do this, muscular waste is not to be dreaded.

The practice of stuffing patients suffering from wasting disease with foods rich in nitrogen seems to be the great desideratum with the majority of doctors; and for what reason I cannot see, unless they are still laboring with the ancient idea that oxidation means muscular waste, and that this waste must be constantly repaired in order to keep up the muscular volume. Hence the ingenuity of the chemist is sorely taxed to get up peptonoids as rich as possible in muscle-forming elements—foods containing as much nitrogen as possible; when the simple fact that the average human body contains but about four pounds of nitrogen, and the other fact that nitrogen oxidizes about as slowly as steel rusts away, and that when muscle is once formed it lasts (when the system is freely supplied with carbon) almost indefinitely, should lead medical men to the consideration of that class of foods which supply force, and lose sight for the time being of nitrogen-foods, which I find far more troublesome to exclude from the diet of the invalid than to get into it.

The food of the monkey in his native wilds is almost exclusively nuts, fruits, and roots, yet he develops a quality of muscle unknown to the structure of man; and, small as is the quantity of nitrogen contained in fruits and nuts, still there is abundance for the repair of muscular waste, and also for all bodily secretions. Hence it seems to me that all this reaching for peptonoids is a blind effort to feed the patient, when, in truth, he actually starves upon such so-called dietary.

We find in the human body about forty-eight pounds of carbon and nearly one hundred pounds of oxygen; not only so, but that these elements are constantly and unsparingly called into use in every thought and act of our lives, while the nitrogeneous elements of the body form the structures within and upon which carbon and oxygen liberate the heat (force) stored within the one and set free by the presence of the other. This being true, it seems that the physician's first duty toward his patient suffering with that class of malady rendering a sufficiency of these elements impossible to obtain without artificial assistance, is to see that such assistance is promptly rendered by supplying in some manner the necessary running power so essential to the well-being of each and every function in life.

Let no one suppose that I do not value albuminoid foods. In the healthy man they are powerfully sustaining, containing, as they do, nearly seventy per cent. of hydrocarbon, and, in order to free that hydrocarbon from the nitrogen present, calling into use the highest quality of vegetative force, thus causing the expenditure of a far greater quantity of nerve-power upon the liver than any other food known; but given a torpid liver, and albuminoid food should be called by another name, as it is no longer food.

If it be true, and the best physiologists of to-day dare not dispute it, that peptones must pass, with the portal blood, not only through the liver but be split up and made into new compounds within that organ, how absurd to load the alimentary canal with such material when the liver is powerless to act upon it, and the fact of predigestion cuts no figure in the matter; for digestion means liquefaction in order that peptone may pass from the intestine into the portal circulation. For peptone is no sooner admitted to the portal blood than it is at once dehydrated and albumen enters the liver as albumen, and every particle not dehydrated enters the general circulation and is removed by the kidneys, and from this source alone has the false diagnosis of "Bright's disease" arisen in thousands of cases. As before stated, large quantities of oxygen are necessary to oxidize peptonoid foods; yet could our patient breathe tons of this life-giving gas, where a torpid liver stands in the road these elements could never meet. Hence, when fatty matter cannot be assimilated, and on account of liver disease proteid foods cannot be assimilated, muscular tissue must be oxidized to furnish heat (force) for bodily function; hence the rapid and extreme emaciation in some cases of consumption wherein a few months closes the scene with only skin and bone remaining. Proteid compounds, given either by mouth or rectum, are incompatible with a seriously diseased liver, therefore I have been driven, by years of vexatious disappointment, to seek other means of getting on satisfactorily with this class of patients. Proteid food is a failure, and hundreds of patients cannot swallow fatty matter in any form, unless it is smuggled past the oversensitive palate in the form of an elegant emulsion; and then the pancreatic and liver failure renders lacteal endosmoses about *nil*, for it is a well-ascertained fact that biliary secretion aids the assimilation of fats in three ways: By increasing peristaltic action; by moistening the mucous membrane of the intestine with an alkaline secretion; and last, but not least, by securing absolute antisepsis of the intestinal contents during the digestive process. So when this important secretion is not present, fats, by being absorbed too slowly or not at all, decompose into a rancid, putrescent mass, and are ejected from the bowel, too often accompanied with colliquative diarrhœa.

There are various elegant preparations which, as emulsions, leave nothing to be desired, but, given by mouth, they are open to the same objections as above stated. I have used these for rectal alimentation, followed by oxygen-injections, with great satisfaction; they are nicer emulsions than I can make, as it is most difficult to find a strictly reliable pancreatin, and when you think you have a good article, perhaps the next specimen of the same make or label will be inert.

Let no one suppose I intend to subject my patient to the carbo-oxygen treatment for long, or to the exclusion of other means of cure. It is simply intended to pick the patient up and enable the flagging energies to take new hold upon the vegetative processes of life, to give power, by these concentrated force-producing elements, to enable the feeble digestive organs to again resume their wonted function. Nor do I find it necessary to resort to the treatment for any great length of time, as it does its work promptly and satisfactorily, restoring appetite and digestive power in every case which I have thus far submitted to it.

How is the treatment given?

Having selected a proper subject for treatment (I do not attempt to raise the dead), I prepare fresh oxygen-gas, which I keep in a zinc or galvanized-iron reservoir over water. I fill a three-gallon rubber-bag, of which a number should be kept on hand; I next connect the bag with my injector (a common rubber bulb-syringe makes a good one), connect this with the wash-bottle, fill the bottle two-thirds full of pure water, attach the long rubber-pipe to the exit tube, to which connect the female tube of a common syringe. Everything must be absolutely clean and air-tight; these are the essentials for using the gas. As to the carbon, I use a long, open-mouthed, glass syringe, modelled after Professor Thomas' artificial leech for dry-cupping the womb, holding three to four ounces. Having my emulsion ready, I place my patient upon his back with the nates resting well forward over the edge of the operating-chair; filling the syringe by suction, I gently pass it beyond the internal sphincter, when I slowly express the contents, one, two, or three ounces, as I desire, into the bowel; then directing the patient to contract the sphincter, I withdraw the instrument, allowing my patient to rest twenty to thirty minutes. I next introduce the gas-pipe, having first contracted the bulb once or twice to expel the air from the tubes. I slowly inject from one to six quarts (vol.), depending on the capacity of the abdomen, the condition of stomach, liver, kidneys, etc.; for if there is much tenderness of any of these organs, the pressure of the gas will cause pain; no definite rule can be given as to quantity. I watch my patient, and when I notice marked fulness of the abdomen, with restlessness of patient, I stop. The treatment may be given twice daily, but I find once a day quite sufficient in most cases.

Time to give the treatment.—The bowel should be emptied and treatment given about three hours after the breakfast-hour. In conjunction with this treatment I use small doses of ferri sulph. exsiccat., say half a grain at ten and four o'clock daily, largely diluted in pure water, say eight ounces; besides, I encourage my patients to drink freely of water and bathe often. As we increase the quantity of iron in the blood, we increase its capacity to utilize oxygen, and it should be remembered that in every case of anæmia, where a chalybeate course brings color to the pallid cheek, that it is oxygen and not iron that reddens the blood.

As soon as possible I encourage my patient to eat light hydro-carbonaceous food, followed, as soon as admissible by some egg-albumen, chicken, fish, etc. Meanwhile I put him upon the inhalation of dilute oxygen-gas, one part oxygen to four of pure air, drawn through water to the reservoir. From the reservoir I have this mixed gas drawn through an inhaling bottle half filled with oil of turpentine; this adds ozone to ordinary oxygen, and renders it surprisingly active. Care should be used in giving this ozonized gas, as, if there is destruction of bronchial epithelium, annoying irritation is set up, with aggravating cough; the inhalations should be given slowly, free respirations of air allowed meanwhile. The first effect of the gas so used is that of a sedative; the pulse becomes slower and fuller, followed in an hour or so by a feeling of greater strength and a desire to get about; there is no excitement produced, but after an hour or so a general sense of well-being becomes manifest. I believe I have herewith given the easiest and safest method for ozonizing oxygen, and so used, with nit. monoxide, it should be a successful remedy for asthma and hay-fever.

And now, to conclude, will the medical profession proper take hold of these facts and use them, or shall they be relegated to the use of the oxygen-parlor frauds that infest the cities all over the land?

And now another word to the medical profession: Carbon and oxygen are the great force-producers in nature; life itself is simply an aggregation of these forces individualized. They bring us into the world, sustain and vivify us while in health; how, then, can we longer intelligently ignore them as therapeutic agents in disease?

RULES FOR FAT PEOPLE AND FOR LEAN.—To increase the weight: Eat to the extent of satisfying a natural appetite, of fat meats, butter, cream, milk, cocoa, chocolate, bread, potatoes, peas, parsnips, carrots, beets, farinaceous foods, as Indian corn, rice, tapioca, sago, corn-starch, pastry, custards, oatmeal, sugar, sweet wines, and ale. Avoid acids. Exercise as little as possible; sleep all you can, and don't worry or fret.

To reduce the weight: Eat to the extent of satisfying a natural appetite, of lean meat, poultry, game, eggs, milk moderately, green vegetables, turnips, succulent fruits, tea or coffee. Drink lime-juice, lemonade, and acid drinks. Avoid fat, butter, cream, sugar, pastry, rice, sago, tapioca, corn-starch, potatoes, carrots, beets, parsnips, and sweet wines. Exercise freely.—Kansas City *Medical Index*.

Progress of Medical Science.

The Utility of Gelsemium.—Gelsemium sempervirens is not as frequently employed, according to Dr. Garland (*Boston Medical and Surgical Journal*, September 13, 1888), as it should be. The eclectics have used it largely for a long time, and many a celebrated eclectic febrifuge has owed its efficiency to this powerful drug. Dr. Garland says that in those crises of cerebral excitement which were formerly combated by assafœtida and valerian, he knows of no drug which can excel gelsemium. Inasmuch as it affects the motor regions of the nervous system before the sensory, it is usually necessary to push its administration until diplopia and heaviness of the lids appear, in order to reach satisfactory results.

In the early stage of acute bronchitis when the cough is disturbing, tubes are dry, and there is pain across the chest, gelsemium will relieve this distress, start up the bronchial secretions, thereby furnishing material for expectoration and diminution of the inflammatory tension.

The dose of gelsemium depends upon the preparation used and the results which one desires to obtain. For the relief of neuralgias one should give three to five drops every half-hour or every hour, according to the intensity of the pain. To produce sweating, one drop every half-hour is sufficient, but the patient should, of course, be well covered up in bed, and protected from the cooling effects of surface evaporation. One drop of the fluid extract every hour will relieve the cough and discomfort of acute bronchitis, and fractional drops can be used as above cited. The tincture of gelsemium is slightly weaker than the fluid extract. The active principle in gelsemium is gelsemin, which can be given in one-quarter to one-half grain doses, but the author prefers the plain drug itself. For convenience the extract and tincture can be prepared in tablet form of one minim each, and then dissolved for fractional doses.

Dr. Garland thinks that the advantages which gelsemium can legitimately claim are: 1. It has an agreeable taste, and is not repulsive to adult or child. 2. It does not irritate the stomach or bowels. 3. It produces no depressing after-effects from ordinary doses. The sleep is natural and the patient awakens refreshed. 4. In ordinary doses it causes no depression of the heart, and it can be used in all forms of organic disease of the heart. 5. It does not create a habit. There is no depression of nerve-centres following its use, and therefore no craving for more of it. 6. Its toxic symptoms are very characteristic and striking, and they appear early, so that plenty of warning is given.

Successful Treatment of Carotid Hemorrhage.—Dr. Treves has reported a case of this kind, as follows (*The Lancet*): A man was brought to the London Hospital bleeding profusely from a deep wound in the neck, about the level of the great cornu of the hyoid bone. While attempting to open a soda-water bottle the bottle burst, and a fragment of glass was driven into the neck. The cut made was less than one inch in length. The glass had been removed. The bleeding had been very profuse, and was arterial. The patient was blanched and almost insensible. The radial pulse could scarcely be felt. The bleeding was for the time checked by pressing a tampon against the wound. It was obviously useless to attempt to find the bleeding point while blood was welling up from so deep a wound. He, therefore, at once exposed the common carotid artery through a lower incision and placed a catgut loop around it. Traction upon this arrested all bleeding. The patient was placed in bed and surrounded with warm bottles. His condition was so grave that he did not feel disposed to search for the bleeding point. Traction upon the loop was maintained for half an hour. On relaxing the catgut no bleeding took place, and it never again recurred. The loop was left *in situ* for four days, when it was removed. The man, who was in vigorous health at the time of the accident, made a rapid and uninterrupted recovery. Dr. Treves supposed the bleeding to have come from the superior thyroid artery.

Rectal Impaction from Nut-shells.—A case of intestinal obstruction, from a cause which would appear to be unique, has come under the observation of Dr. Lockhart Wilson, of Duns, Berwickshire. He was called to see a boy, seven years of age, living among the Lammermoor Hills, who, as his father thought, was suffering from obstruction of the bowels. A week previously he had eaten a large quantity of hazel-nuts, and had swallowed the shells as well as the contents. For several days past he had had intense desire to defecate, but with no result, and seemed to be suffering excruciating pain. On rectal examination, about an inch and a half above the anus was found an impacted mass, as large as two fists, very hard, with the sharp edges of shells presenting here and there. By the use of warm oil the mass was gradually got away in small pieces, not without some abrasion of the rectal walls. It consisted almost entirely of shells agglutinated together by a small amount of hard fæces. For several days after there was paralysis of the sphincter ani, and consequent incontinence of fæces, but otherwise the child made an excellent recovery. The wonder is how such a large quantity of shells, with sharp-pointed and cutting edges, passed through the bowels without causing any inflammatory trouble.—*The Practitioner*, September, 1888.

The Diminution of the Number of Blood-corpuscles in Enteric Fever.—Dr. Leclerc, in attempting to estimate the relative value of various methods of treatment in enteric fever, has undertaken to estimate the numbers of the blood-corpuscles. In all cases he found a diminution during the fever, amounting, according to the method of estimation of Malassez, to a reduction from about 5,500,000 per cubic centimetre to 4,500,000 or even 3,500,000. The results of observations of ten cases, some of which were treated with cold baths only, some with antipyrin or antifebrin, do not show a complete correspondence to the treatment used or to the general severity of the case, but tend to the conclusion that antifebrin produces the greatest diminution, antipyrin a less decrease, and the cold baths the least decrease in cases of about the same severity.

Electricity in the Vomiting of Pregnancy.—Dr. Gunther, or Montreux, mentions five cases of vomiting of pregnancy in which he found electricity of the greatest service. In none of the cases could any pathological condition of the uterus or its appendages be detected. Four of the cases were primiparæ. The remaining case was that of a woman who had had two confinements previously; in her first pregnancy she had suffered from sickness, but not in her second; in the earlier months of the latter, however, she had suffered from severe pruritus of the thighs. Some improvement only was obtainable by regulating the diet, but this was not of any long duration. Narcotics, too, had only a temporary effect. In the absence of pathological indications, we must seek for the explanation of the vomiting in the reflex action between the uterine and gastric nervous supplies, just as the tonsils are enlarged in asthma because of the relation between the cranial and gastric nerves. The female genital organs may be considered as related to other parts of the body from a vaso-motor point of view, and the occurrence of vomiting is probably sometimes to be explained from a consideration of that circumstance. In severe cases a definite degree of sensitiveness is present, and Dr. Gunther believes that there is a functional neuralgia of a reflex nature. He applied the anode of a constant current in the form of a sponge, in a metal case covered with rubber to the cervix. The cathode was a plate about four inches by five inches. This was applied over the spine, between the eighth and twelfth dorsal vertebræ.

It is important to see that the current is not intermittent, and to use only one of a low strength. He commenced with two and a half to three milliampères, and never increased the strength higher than five milliampères. Each sitting lasted from seven to ten minutes. The vomiting ceased in four days, at the most, in all the cases. As some degree of nausea remained, the treatment was continued for some weeks.—*The Lancet*, August 25, 1888.

The Influence of Bacteria upon the Digestion of Children.—Baginsky states that the bacterium of lactic fermentation causes the production of acetic acid and acetone, as well as lactic acid. This formation goes on without oxygen and is not hindered by the bile. The neutral lactates are changed to butyric acid; starch is not changed to sugar, nor is casein or albumin decomposed. The gases formed when acetic acid is produced are carbonic acid, hydrogen, and methane.

He proposes to style this bacterium the acetic bacterium. He further found that this bacterium is destroyed by acetic acid. In examining the stools of children suffering from *cholera infantum* he isolated a bacterium which produced green stools (the germ of Hayem and Lesage) and also a bacterium growing in white colonies. Both of these liquefy gelatine and both are inhibited in their development by the acetic bacterium; this germ has the property of preventing the growth of pathogenic germs in the intestine.

Baginsky considers that only the primary manifestations of *cholera infantum* are caused by bacteria, and that the secondary, severer phases result from the extensive anatomical lesions in the intestine which have occurred. It is evident that the treatment of a given case will depend upon the stage of the disease. He found calomel, boric acid, and resorcin prevent the growth of the acetic bacteria; naphthaline and iodoform are inert. If the case is seen early, when acetic fermentation is excessive, these remedies and the withdrawal of milk are indicated. If pathogenic bacteria have accumulated in the stomach or intestines, irrigation with antiseptic fluids is advised. Each case must be studied separately, and interference with the conservative processes, as shown in the inhibitory action of certain bacteria, should only be undertaken intelligently.—*The American Journal of the Medical Sciences*, October, 1888.

Successful Case of Splenectomy.—Dr. Carlo Liebman, of Trieste, has described a case in which he successfully removed an enlarged and floating spleen (*The British Medical Journal*, September 15, 1888). The patient was a woman, aged twenty-eight, who, in her third pregnancy, noticed a hard, round tumor in her abdomen, toward the left side, below the level of the umbilicus. For some time the swelling remained stationary, but five months before she came under the care of Dr. Liebman it began to grow rapidly and to cause great pain, especially when she moved about. She became quite unfit for work, and on November 24, 1887, was admitted into the Ospedale Civico. On examination, the liver and spleen appeared to be normal in size, the area of dulness corresponding to what was supposed to be the latter, extending in the left axillary line from the eighth to the tenth rib, while its vertical diameter seemed to be about three inches. The abdomen contained a roundish but somewhat oblong tumor about the size of a small adult head, which appeared to rest on the upper margin of the pelvis. The mass, which was situated rather to the left of the middle line, was evidently intraperitoneal. Its surface was smooth, with a kind of notch in the middle. It was movable in every direction, and could be carried up to the margin of the ribs on the right side as well as on the left, but could not be pushed into the hypochondrium beyond that point. There was no adhesion to the abdominal wall in front. A distinct systolic *bruit* could be heard over various parts of the mass. The uterus was normal, but followed the tumor when the latter was pushed toward the right, but not when it was carried over to the left side or in an upward direction. The tumor could be freely handled and moved about without pain. There was no albumin in the urine, of which rather more than a litre was passed in the twenty-four hours, and there was no disturbance of digestion. A diagnosis of ovarian or mesenteric tumor was made, and laparotomy was determined on. On December 13th Dr. Liebman opened the abdominal cavity by a median incision seven inches in length, and divided the peritoneum, which was remarkably thin and transparent, along the whole length of the wound. The ovaries were atrophied, and neither they nor the uterus had any connection with the tumor. On drawing the latter out of the abdomen it proved to be the spleen, enlarged to four times its natural size, while *in situ* its convex surface had been directed upward and forward, and was adherent for a great part of its extent to the omentum. The mesenteric vessels were tied, and all the attachments of the tumor carefully divided between double ligatures, till only the pedicle (formed by the vessels, etc, entering the hilium), which was as thick as the little finger, remained. This was then divided into three bundles, each of which was tied separately, the end of the last ligature being finally passed round the whole for additional safety. The pedicle was further secured by a second ligature two centimetres and a half higher up, and, lastly, it was again tied close to the spleen. It was then divided between the two last-mentioned ligatures, and the spleen removed. Having satisfied himself that there was no blood in the peritoneal cavity, the operator closed the abdominal wound with seven deep sutures taking in the peritoneum, and five superficial ones. A Listerian dressing was applied. The patient rallied from the operation, and, with the exception of a good deal of tympanites, did well till the eighth day, when the sutures were removed, the wound having healed without suppuration. On the night of December 21st menstruation began. A good deal of pain accompanied the discharge, and there was some pyrexia. Soon extensive parametritis set in, which, however, yielded to general treatment. The patient remained weak and anæmic for some time, but finally left the hospital completely cured on March 25th.

Ointment of the Nitrate of Mercury in Boils and Felons.—During the last six years Dr. Robert Kenner has used successfully this preparation as an abortifacient of boils and felons. He claims that through its agency he has been able to abort nearly all cases that came under his care before suppuration had commenced. The application of the ointment is not painful, and in about twelve hours is followed by a peculiar drawing sensation, after which there is a complete cessation of all uneasiness. In treating felons the entire finger should be covered with a coating of the ointment about one-eighth of an inch thick, and then enveloped in a piece of thick sticking-plaster. This dressing is allowed to remain for twenty-four hours, after which time further treatment is unnecessary.—*Therapeutic Gazette.*

Treatment of Aneurisms by Iodides and Antipyrin.—At the Académie de Médecine M. Sée recently read a paper on the treatment of aneurism by iodides and antipyrin. Seventeen cases were brought forward to confirm the efficacy of the treatment, and in all a marked decrease in the size of the tumor was observed, and the oppression, sense of suffocation, laryngeal dyspnœa, accompanied by aphonia, derived from pressure on the recurrent nerve, entirely disappeared. All these happy results M. Sée did not hesitate to attribute to the iodide of potassium. The iodide of sodium, contrary to the opinion of Dr. Huchard, was not as good as the iodide of potassium. As to antipyrin, the learned professor found that it rendered the impulse of the heart more calm, and thus permitted the blood to complete its coagulation in the sac, and further, the painful sensation of tightness so often experienced by patients afflicted with this affection was known to be completely relieved by its use.—*The Medical Press.*

Salicylic Acid in Metrorrhagia.—Dr. Felici has found salicylic acid to arrest the flow in two cases of metrorrhagia in a wonderfully short time, and thinks it should be tried by other medical men in similar cases. His first case was one of carcinoma, where the hemorrhage had been constant and profuse, and had defied all ordinary styptic remedies; a plug of carbolized cotton-wool, soaked in a solution of salicylic acid, was applied to the uterus, and completely arrested the hemorrhage within a few minutes. The second case was one of simple metrorrhagia during the menopause, but of so violent a character that the patient became collapsed. Ordinary remedies were tried, with merely temporary effect. Finally, Dr. Felici introduced into the uterus a dossil of cotton, well soaked in a concentrated solution of salicylic acid, on the end of the uterine sound. This arrested the hemorrhage in a few seconds, and no return occurred.—*The Lancet.*

Idiopathic Dyspepsia.—At a recent meeting of the Académie de Médecine, M. Clozier read a paper on the etiology of primitive dilatation of the stomach and idiopathic dyspepsia. Regarding the former he would recognize four principal causes—the vertical attitude of man, the bad hygiene of the human stomach, morbid secretion of the mucous membrane, and the stretching of the walls of the organ. When the stomach is distended after a copious repast, the ingested food remains naturally a much longer period in its cavity; an abundant secretion of mucus is the result, and dyspepsia with all its annoyances is thus engendered.—*Medical Press.*

The Treatment of Acne.—At a recent meeting of the Berlin Medical Society, Hr. Isaacs gave an address on acne, principally discussing the treatment of the disfigurement, and showing patients. After describing the various methods of treatment, he remarked that while employed in Lassar's klinik, where every form of treatment was tried, he invariably fell back on a ten per cent. napthol ointment, composed of napthol 10, sulph. precipit. 50, saponis virid. and vaselin, each 20 parts. The ointment was applied to the affected parts, and kept there from half an hour to an hour, and then removed with lint or oil. The following day there was slight redness and scaling of the skin. The procedure was repeated until the peeling was completed, which usually took place in from eight to fourteen days. Lately he had adopted the use of a resorcin ointment in obstinate cases: Resorcin, 2.5 to 5.0; zinc oxid. and amyl, 5.0; vaselin, 12.5. M. To be made into a soft paste. The ointment to be put on at night and allowed to remain on till morning. He had seen very good results in the ten or fifteen cases in which the treatment had been employed.—*Medical Press.*

Cardiac Dyspnœa.—Dr. Fränkel has published his views on this subject, a *résumé* of which appears in the October number of the *American Journal of the Medical Sciences.* He says that dyspnœa appears in very different forms in the different heart diseases, depending on the nature of the affection. It is sometimes premonitory, but is then slight and only occasional; and disregarding this, we may distinguish two forms of severe dyspnœa, the *continual* and the *asthmatic.* The first is especially well seen in stenosis of the mitral valve. This lesion is the least apt to attain complete compensation, and even when this occurs it is by hypertrophy of the right ventricle and necessarily with overfilling of the pulmonary system. The distended pulmonary capillaries project into and narrow the cavity of the alveoli, and this contraction of the alveolar space, together with the slowing of the blood current, and the lessening of the proportionate surface exposed to oxygenation, produces the continual dyspnœa. Digitalis in this lesion sometimes acts very badly, since by stimulating the right ventricle and sending more blood to the lungs it only increases the shortness of breath. Other cardiac affections also are accompanied by continual dyspnœa, as, for example, cases of progressive failure of the left ventricle with consequent engorgement of the pulmonary system; as is seen in the last stages of cases of "cardiac overstrain," or in heart diseases resulting from psychic depression. Cardiac asthma, on the other hand, is seen most typically in hypertrophy of the left ventricle, with abnormal resistance in the blood-vessels, resulting from arterio-sclerosis. The asthmatic attack comes quite suddenly and usually at night, waking the patient from sleep, and is generally very severe. The lungs are found full of coarse râles, and respiratory pauses may occur like those of Cheyne-Stokes respiration. The affection often resembles bronchial asthma greatly, but may be distinguished by the high tension of the vessels, the absence of expiratory dyspnœa, and often by the discovery of a dilated left ventricle, though this is not always easily detected, owing to an increase in the volume of the lungs. This enlargement is due to the fact that through the narrowing of the arteries the blood is driven into the venous system, or, rather, into the lungs and the left auricle. Hence there is a permanent engorgement of the pulmonary circulation, even when there is complete compensation. The sudden asthmatic attacks are probably due to a sudden temporary insufficiency of the left ventricle, brought about by psychic emotion, increasing catarrh, or some other cause. The heart is already doing its utmost. and this disturbance of the balance produces increased passive congestion and consequent dyspnœa. Autopsies have shown that the heart muscle is of normal structure, and it would, therefore, seem likely that the failure is due to paralysis of the cardiac nerves or ganglia. Fränkel cannot accept the theory of Basch, that cardiac dyspnœa is due to a rigidity of the lungs from their being overfilled with blood; this producing an insufficiency of the respiratory muscles. Regarding the therapeutics, the author repeats what he has formerly said in praise of morphia and digitalis in combination. The former diminishes the arterial tension, prevents the exhaustion of the respiratory centre by the continued dyspnœa, and cuts short the asthmatic attack, while the latter stimulates the ventricle to greater activity. Calomel may also be employed for its diuretic and purgative action, thus depleting the system; and though somewhat uncertain, it always benefits that patient to whom it has formerly done good. Strophanthus has been of no value in dyspnœa in the author's experience, except in those cases in which it produces free diuresis. As regards uræmic and dyspeptic asthma, the former is simply cardiac, and has nothing directly to do with uræmia. Cases of the latter have been reported by Henoch, and seem to depend on the presence of undigested masses in the stomach, the affection being relieved by vomiting after lasting one or two days.

Fissure of the Cervix Uteri.—"Fissure of the Cervix" is the name given by Dr. T. H. Reilly, of Fair Haven, Vt., to a condition of incomplete laceration which he has observed in several women recently. He has successfully treated this condition, which appears to produce symptoms in every respect resembling those usually found in true lacerations, by cauterizing the existing granulations and employing medicated tampons. Operative interference appears to be unnecessary. It strikes us, however, that fissure of the cervix is a needless refinement of diagnosis. Incomplete laceration is the good old name for the same condition.

Nussbaum's Treatment of Erysipelas.—According to Professor Nussbaum the erysipelatous parts, previously rubbed with a pomade of lanoline and icthyol—equal parts—are enveloped in salicylated cotton. It will be found, the day after this application, that not only has the erysipelas not advanced, but that there has been a notable amelioration in all the morbid symptoms. The swelling, the redness, and the pain have very much diminished. It is hardly ever necessary to continue the application for more than three days.—*Allgemeine Wiener Med. Zeitung.*

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, November 10, 1888.

THE CAUSE OF THE HEAD-DOWNWARD PRESENTATION.

IT always has been, and always will be, a matter of general and scientific interest to know why ninety-seven per cent. of humanity has been carried for nine months of its life head downward. The simple yet dramatic solution of the question by the ancients was that the child sat upright in the womb until full term, when he cleverly executed a somersault into the L. O. A. position and started on his way through the pelvic strait. This view fully satisfied the followers of the obstetric art for many hundreds of years, and it was indeed not much worse a theory than some of its successors. Dr. James Foulis, in the *Edinburgh Medical Journal* for September and October, 1888, gives us an elaborate discussion of the cause of the head-downward presentation.

Dr. Foulis thinks that gravitation and muscular movements of the fœtal limbs together produce this position, the muscular power in the lower limbs being the main factor.

"These muscular movements," says Dr. Foulis, "are not made with the object of determining a head-downward position of the child, or of putting its body into the most comfortable position in utero, but this head-downward position is the natural and ultimate consequence of the child's head gliding along the inner curved surface of the uterus while its body is being propelled forward by the forcible extension of the lower limbs against a more or less resisting and opposing surface. In this way the assumption of the natural or head-downward position of the child is a vital act. Death of the child in utero at any period may result in any presentation, normal or abnormal, according to *physical* laws."

Dr. Foulis thinks that the first cranial position of the head is also the result of muscular movements in its lower limbs after the child has assumed the head downward position in the way he has described.

The conclusions arrived at are as follows: The head downward position of the child in utero is the necessary and ultimate consequence of the continued extension of the child's lower limbs against the most resisting parts of the uterine sac. The first cranial position of the child's head is the necessary and ultimate consequence of the continued extension of the child's lower limbs against the most resisting part of the uterine sac in its upper part—namely, that which lies in the right hypochondrium—after the child has assumed the head-downward position.

A DEFECT IN MODERN SURGERY.

THE paper by Dr. David W. Cheever, of Boston, on "Shock," of which we gave an abstract in our report of the Congress of American Physicians and Surgeons, brings up a point which deserves much more than casual attention.

Dr. Cheever shows that modern operative methods, though so much superior to the old ones in most respects, yet tend to cause secondary shock. As he puts it:

"Anæsthetics annul pain, but end in nausea.

"Operations under anæsthetics are needlessly prolonged and exhausting.

"Modern dressings are tedious and chilling.

"Pain and bleeding are *less*. Slow cutting, nausea, exposure, low temperature are *more*. Primary shock is diminished; secondary shock is increased."

Patients are now frequently from one and a half to two hours on the operating-table, and three hours more in recovering consciousness. Operations of secondary magnitude are sometimes made so long that the patient dies from shock.

Patients are not given food before an operation to prevent nausea, and they often cannot retain food after an operation for a long time on account of nausea. Here, then, is another defect in modern surgical practice. Lowering of temperature is another thing which occurs after operations. The thermometer frequently falls to 96° or 97° F., and may reach as low as 95° F.

The modern surgical toilet of wounds is depressing, exhausting, devitalizing.

Finally, nausea and vomiting are still present in modern surgery, and are often dangerous indications of depressed vitality.

It is very evident that modern surgery is not yet a perfect art, and Dr. Cheever's paper calls attention to the fact that all is by no means done when perfect asepsis is secured, or wound infection prevented.

The practical directions given for the purposes of lessening the element of shock are these:

1. Wait for reaction.
2. Never neglect to calm those suffering mental shock by a cheerful word and personal presence.
3. Give alcohol, either spirits or wine, a quarter of an hour before the anæsthetic.
4. Make the anæsthesia short; never begin it until everything is ready; suspend it during the less painful dressings. Consciousness returns *tardily*. We keep up the anæsthetic longer than is necessary.
5. As rapid an operation as can prudently be done.
6. As short a dressing as is practicable.
7. As a cardinal point, avoid *chilling* the patient.

To promote reaction after the operation:

1. Persistent and *carefully* applied *dry* heat. (Be *over-careful* about accidental burns.)
2. Liquid nourishment, combined with a stimulant and a little laudanum, by enema.
3. Subcutaneous injection of brandy.
4. Aromatic spirits of ammonia by the mouth. Champagne is sometimes retained when other things are rejected.

5. Black coffee and brandy, the stimulant *par excellence*, when it can be retained on the stomach.

6. Quiet; a horizontal, or more than horizontal, position; sleep; assurance that all is over and doing well.

RESTORATION OF VOICE AFTER DESTRUCTION OF VOCAL CORDS.

Among the cabled reports to the New York *Herald*, having reference to the Mackenzie controversy with the German doctors, we notice the interesting case of Mr. Montagu Williams, who was successfully operated on for complicated growths in the larynx, involving destruction of the vocal cords. The most interesting feature of the case was that Mr. Williams had a partial return of voice, due to a regrowth of the vocal cords, but the patient was never capable of returning to his profession of barrister, or of speaking in a public court.

This case is mentioned as something exceptional and extraordinary, but we may state that we have a case on record in this country in which the symptoms were more aggravated, and not only was the case successful, but the patient lived for many years, and had a complete restoration of voice, the patient, a young man, declaring that, with the exception of its being a little rough, his voice was as good as ever.

This operation was performed by Dr. J. Solis Cohen, of Philadelphia, who reported it fully in The Medical Record, vol. iv., page 244, to which reference is made for details of the case. A brief mention of the case is also made in Dr. Cohen's valuable work on "Diseases of the Throat," published by William Wood & Co. On reference to page 446 of this book, we find three illustrations, showing the laryngeal growths which were removed by thyrotomy, after tracheotomy; the appearance of the parts some months after the operation; and, thirdly, the appearance of the parts some years after the operation, showing the vocal cords in apparent normal condition. Dr. Cohen states that "he removed from the larynx of a young gentleman a large epithelioma, which was upon his left vocal cord and ventricle, as well as two much smaller growths from the right vocal cord, after the previous performance of tracheotomy." He adds: "An important feature in connection with this case consists in the fact that there was a reproduction of tissue in the left vocal cord, the anterior portion of which had been purposely sacrificed in the removal of the growth, and from which an expansion took place to the other cord anteriorly. This shows us that the vocal cords, or a substitute for them, can be reproduced, and seems to confirm the view that they are mere duplicatures of elastic membrane, and not special structures." As we have stated, the patient's voice, although a little rough, was pronounced as good as ever it was.

SULFONAL IN MENTAL DISEASE.

The value of sulfonal as a hypnotic in ordinary cases of sleeplessness from fatigue, worry, etc., seems to be now pretty well established by the experience of many both here and abroad. But it is probable, to judge from some trials made by Dr. G. Algeri, that it will prove to be of equal service in the insomnia of mental disease. This observer reports fifteen cases treated by him with the happiest results in the Asylum for Insane Criminals of Ambrogiana (*La Riforma Medica*, October 8, 1888). The list embraces cases of acute mania, imbecility, melancholia, dementia, epilepsy, hallucinations, and acute alcoholism. In almost every instance a calm, healthy sleep followed the exhibition of from fifteen grains to a drachm of sulfonal. The slumber was accompanied by no disturbances of circulation or respiration, and lasted from two to five hours or longer. In a few cases it was found necessary to repeat the dose before sleep was produced. Even with drachm-doses there were no disagreeable after-effects beyond drowsiness and a feeling of lassitude the following day. The digestive functions were not disordered. But although the drug would appear, from these and other trials, to be innocuous, a word of caution will not be out of place. We are not yet sufficiently familiar with its effects to assert with confidence that it can do no harm, and any substance that is able to calm maniacal excitement and produce sound slumber within an hour is not one that can be given recklessly, at least until we are well acquainted with its mode of action.

THE USELESSNESS OF ANTIPYRINE IN SEA-SICKNESS.

It is the common fate of all new drugs to be speedily tried in sea-sickness. And the newer the drug the better the results usually appear to be, at least for a time. When the novelty has worn off the drug is usually found to have become strangely inoperative. The multicurative antipyrine was at first supposed to form an exception to this rule. But evidence is now at hand which shows that even antipyrine fails to cure sea-sickness, and that we must still undertake our ocean voyages with the prospect of gastro-intestinal retrostalsis before us.

One of the latest antipyrine statements is found in a correspondence published in the *Boston Medical and Surgical Journal* of October 11, 1888. Dr. Stephenson writes that, "It having been reported by O. Bonnet that antipyrine in a dose of thirty grains a day sufficed, nearly always, to prevent sea-sickness, E. Rollet made numerous observations, *in re*, during a voyage from Marseilles to Oran. There were about three hundred passengers on board the vessel. When the ship began to pitch, and the first symptoms of *nausea* were perceived, sixty persons at least took from fifteen to forty-five grains of antipyrine. Of the whole number, four only were enough free from *mal de mer* to sit through dinner. On the return trip the result was essentially the same. It is affirmed that the drug was taken according to the directions given by O. Bonnet.

"This experiment shows how difficult is the exact *seeing* of things which at first appear very simple."

THE INFLUENCE OF TOBACCO-SMOKE UPON INFECTIVE MICRO-ORGANISMS.

Studies upon the chemical, physiological, and toxicological properties of tobacco-smoke always excite a wide interest, and often have some practical usefulness. A new line of research has recently been opened by Dr. Vincenzo Tassarini, who, in the *Centralblatt für Bakteriologie und Parasitenkunde*, No. 15, reports the results of an experimental investigation upon the action of tobacco-smoke upon certain pathogenic micro-organisms. Dr.

Tassarini worked under Professor Giaxa, at the University of Pisa. He devised an apparatus consisting of two funnels placed with their mouths opposed, and sealed with paraffine. To each small end of the funnels tubes were attached, suitably arranged so that a cigar could be placed in one end, while the bacteriological smoker inspired at the other. The smoke was thus drawn into the large space made by the funnels, in which was a plate with various cultures of micro-organisms; control cultures were also used. The microbes were subjected to the smoke for from thirty to thirty-five minutes, during which time from 3½ to 4½ grammes of tobacco were used. The micro-organisms tested were the spirillum choleræ Asiaticæ, spirillum Finkler and Prior, bacillus anthracis, bacillus typhi abdominalis, bacilli pneumoniæ, staphylococcus pyogenus aureus, and bacillus prodigiosus.

The kinds of tobacco used were the large Virginia cigars, the large Cavour cigars, the small Cavour cigars, the best cigarette tobacco.

The results show that tobacco-smoke has the effect of preventing the development of some micro-organisms entirely, and of retarding that of others. The Virginia cigars seemed to have the most powerful effect, while cigarette-smoke had only a retarding influence, and did not entirely check the growth of any form.

The following table of the effect of Virginia tobacco illustrates the results more exactly:

Development delayed of bacillus prodigiosus for	72	hrs.
" " " staphylococcus pyogenus aureus for	73	"
" " " bacillus anthracis for	97	"
No development of bacillus choloræ Asiaticæ after......	128	"
" " " " Finkler and Prior "	128	"
" " " " pneumoniæ "	146	"
" " " " typhi abdominalis "	168	"

By first drawing the tobacco-smoke through water it was found to have lost its germicidal properties.

There has always been a vague belief that smoking lessened, to some extent, the danger of infection when one is exposed. Tassarini's experiments give some support to this opinion, so far as the microbes which infect through the mouth and respiratory passages are concerned.

THE HEALTHFULNESS OF OUR COUNTRY AND THE STATISTICS OF AN EXCEPTIONALLY HEALTHY CITY.

EVER since the publication of the census returns for 1880 we have been preparing ourselves to believe that we live in a country that is phenomenally healthy.

It will be remembered that the actual returns then made to the Government showed a death-rate in the United States of only 15.1 per thousand, though the compiler of the report, making allowances for defective returns, placed the actual mortality at a figure not exceeding 18 per thousand. Comparing this ratio with that of other well-known countries, it is seen that we easily stand at the head of the list, as is shown by the returns for the same year, 1880:

England and Wales	20.5
England (rural districts)	18.1
France	22.8
Austria	29.6
Prussia	25.5
Sweden	18.1
Italy	30.5
Switzerland	21.9

In this connection, and at a time of the year when thousands of invalids are inquiring where they shall spend the winter, it is interesting to gather some information in reference to the advantages which our own country offers, especially in sections where, as yet, little is known of their salubrious qualities. Under date of October 12, 1888, Dr. W. M. Yandell, health officer of the city of El Paso, Texas, publishes a report of the mortality in that place during the first nine months of the present year. In a population estimated at 11,000, the total mortality from all causes was only 85, or a death rate of only 7.63 per thousand. Compare these rates with that of the subjoined cities in 1880:

El Paso	7.63
London	22.14
New York	26.47
Providence	19.83
Liverpool	27.22
Paris	26.48
Madrid	40.18
Dublin	35.94
Rio de Janeiro	33.22

It would appear, then, that the rate of mortality has been less than one-third of that of any of these cities, and less than one-half of the rate of any of the countries enumerated, including the United States.

Of the twenty-two causes of death given, it is natural that diseases of the chest should stand at the head, though Dr. Yandell affirms that no cases of consumption originated there. Indeed consumption appears to be a foreign disease that did not carry off a single Mexican, though they are the natives and comprise the poor of the city.

But extraordinary as this showing is, it appears that if invalids who went to El Paso for their health, and deaths by accident be excepted, the actual mortality should be reduced to 59, or 5.36 per thousand, and these returns are all the more wonderful because in all of the great health-resorts, especially those of the winter season, such as Minnesota and Southern California, the number of deaths from lung-diseased alone among persons who have gone there as invalids raises the death-rate vastly above the natural death-rate of the locality. It is plain that the southwestern portions of our country offer great advantages to invalids, and especially to consumptives, for there winter is dry and bracing, and not severely cold; malarious diseases appear to be unknown. Our medical men should inform themselves more fully of its advantages.

ANTISEPTIC TROCHES, to be dissolved in the mouth as a means of prevention against diphtheria, are recommended by Dr. A. Vaumond (*Norsk Mag. f. v. Tagevidensk*), and have been successfully used by him since 1886. The pastilles contain 20.0 boric acid, 1.0 benzoate of sodium, 0.5 to 1.0 thymol, 20.0 borax, 12.5 citric acid, 1.5 citron oil, 0.5 oil of peppermint, with sufficient glycerine, water, gum and sugar to make a kilogram. Five hundred pastilles are made from one kilogram.

ANOTHER PAIR OF TWINS, united like the Siamese monstrosities, was born recently at Kremsier, in Europe. Unfortunately they did not live and have been deposited in alcohol in an anatomical museum.

News of the Week.

Programme of the Twelfth Annual Meeting of the American Academy of Medicine.—The sessions will be held in the Governors' Rooms of the New York Hospital, 8 West Sixteenth Street, New York, Tuesday and Wednesday, November 13th and 14th. Tuesday, November 13th, at 10 A.M.: Opening of Session; Reading of Minutes of Last Annual Meeting; Report of Council; Election of Fellows; Appointment of Committee on Nominations; New Business; Report of Standing Committee on the Requirements for Preliminary Education in the various Medical Colleges of the United States and Canada, by Leartus Connor, A.M., M.D., Detroit, Mich. Reading of Papers: "The Causes and Prevention of the Opium Habit and other Allied Affections," by James C. Wilson, A.M., M.D., Philadelphia, Pa.; "The Influence of the Work of the Illinois Medical Practice Act upon Medical Education," by H. A. Johnson, A.M., M.D., Chicago, Ill.; "The Importance of Practical Obstetrics in the Course of Instruction given by Medical Schools," by Theophilus Parvin, A.M., M.D., Philadelphia, Pa. At 3 P.M.: New Business; Address by the President, Frederick Henry Gerrish, A.M., M.D., Portland, Me.; Reading of Papers: "A Few Words Concerning the Academy," by R. Lowry Sibbet, A.M., M.D., Carlisle, Pa.; "Toleration and Intolerance in Medicine; Codes of Ethics; What Code should the Academy Adopt?" by Henry I. Bowditch, A.M., M.D., Boston, Mass.; "The Relations between the Consultant or Specialist and the General Practitioner," by L. Duncan Bulkley, A.M., M.D., New York. "The Evils of a Medical Dialect Separated Widely from Classical English," by Edmund Andrews, A.M., M.D., Chicago, Ill. At nine P.M.: Annual Collation of the Academy, at Martinelli's, Fifth Avenue. Tickets for the Collation (fixed, by resolution of the Academy, at two dollars each) may be obtained by remitting the amount to Dr. L. Duncan Bulkley, 4 East Thirty-Seventh Street, New York. Wednesday, November 14th, at 10 A.M.: New Business; Treasurer's Report; Report of Committee on Nominations. Reading of Papers: "The Multiplication of Useless Drugs," By C. C. Bombaugh, A.M., M.D., Baltimore, Md.; "The Necessity for Post-Graduate Instruction in the Present State of American Medical Education," by Charles C. Lee, M.D., New York, N. Y.; "Which is the Liberal School?" by Charles McIntire, Jr., A.M., M.D., Philadelphia, Pa.; "The Treatment of Uterine Diseases by other than Surgical Means," by W. F. Waugh, A.M., M.D., Philadelphia, Pa.; "The Famous Historic Masters of the Healing Art were Men of Classical Education," by George J. Fisher, A.M., M.D., Sing Sing, N. Y. New Business; induction of President-elect; Appointments for ensuing year (additional members of Council; Standing Committee on Requirements for Preliminary Education); Unfinished Business; Adjournment.

Officers and Council: President—Frederick Henry Gerrish, A.M., M.D., Portland, Me. *Vice-Presidents*—William B. Atkinson, A.M., M.D., Philadelphia, Pa.; J. H. Baxter, A.M., M.D., United States Army; Thomas J. Turner, A.M., M.D., United States Navy; J. Berrien Lindsley, A.M., M.D., Nashville, Tenn. *Secretary and Treasurer*—Richard J. Dunglison, A.M., M.D., Philadelphia, Pa. *Assistant Secretary*—Charles McIntire, Jr., A.M., M.D., Easton, Pa. *Council*—Traill Green, A.M., M.D., Easton, Pa.; Lewis H. Steiner, A.M., M.D., Baltimore, Md.; Henry O. Marcy, A.M., M.D., Boston, Mass.; Benjamin Lee, A.M., M.D., Philadelphia, Pa.; Albert L. Gihon, A.M., M.D., United States Navy; R. S. Sutton, A.M., M.D., Pittsburg, Pa; Lewis P. Bush, A.M., M.D., Wilmington, Del.; and the President, Vice-Presidents, Secretary, Treasurer, and Assistant Secretary, for the current year, *ex officio.*

The Manhattan Medical and Surgical Society.—At the last meeting of this Society the following officers were elected for the ensuing year: *President*, Edmund C. Wendt, M.D.; *Vice-President*, Thomas L. Stedman, M.D.; *Secretary* and *Treasurer*, Dillon Brown, M.D.

The Washington Obstetrical and Gynæcological Society.—At the annual business meeting of the Washington Obstetrical and Gynæcological Society, held October 19, 1888, the following officers were elected for the ensuing term: *President*, Joseph Taber Johnson, M.D.; *Vice-President*, D. Webster Prentiss, M.D., and W. W. Johnston, M.D.; *Treasurer*, George Byrd Harrison, M.D.; *Recording Secretary*, Samuel S. Adams, M.D.; *Corresponding Secretary*, G. Wythe Cook, M.D.

New York Post-Graduate Medical School and Hospital.—Dr. Joseph O'Dwyer, the originator of Intubation of the Larynx, has been appointed Professor of Diseases of Children in the New York Post-Graduate Medical School and Hospital.

American Public Health Association.—The sixteenth annual meeting of this association will be held at Milwaukee, Wis., Tuesday, November 20th, at 10 A.M., and continue four days. The following topics have been selected for consideration: "The Pollution of Water-supplies," "The Disposal of Refuse Matter of Cities," "Animal Diseases Dangerous to Man," and "Maritime Quarantine, and Regulations for the Control of Contagious and Infectious Diseases, and their Mutual Relations." The following partial list of papers is announced: The President's Address; "The History and Administration of Quarantine in Texas, 1878 to 1888," by R. Rutherford, M.D., State Health Officer of Texas; "The Canadian System of Maritime Sanitation," by F. Montizambert, M.D., Quarantine Officer at Grosse Isle, St. Lawrence River; "Yellow Fever: Panics, and Useless Quarantines—its Limitation by Temperature," by John H. Rauch, M.D., Secretary of the State Board of Health of Illinois; "The Organization of the National Health Service," by Henry P. Walcott, M.D., President State Board of Health of Massachusetts; "State Boards of Health," by Ezra M. Hunt, M.D., Secretary State Board of Health of New Jersey; "The Difficulties and Success of the Public Health Service in Large Cities," by Oscar C. DeWolf, M.D., Health Commissioner of Chicago; "Ontario Sanitary Legislation, its Strength and its Weakness," by John Coventry, M.D., Medical Health Officer of Windsor, Ont., Canada; "The Destruction of Organic Matter by Fire as a Sanitary Measure—Garbage Furnaces," by S. S. Kilvington, M.D., President of the Board of Health of Minneapolis; "Vaccination as a Protection from the Infection of Small-pox," by D. W.

Hand, M.D., President of the State Board of Health of Minnesota; "Tuberculosis, its Origin, Detection, and Control," by D. E. Salmon, D.V.M., Chief of the Bureau of Animal Industry, Washington; "Veterinary Sanitary Work in Wisconsin, with Special Reference to Diseases Communicable to Man," by V. T. Atkinson, D.V.M., State Veterinarian of Wisconsin; "The Relations of Bacteriology to the Discovery and Prevention of Causes of Infectious Diseases among Men and Animals," by Theobold Smith, M.D., of the Bacteriological Laboratory of the Bureau of Animal Industry, Washington; "Popular and Scholastic Education in Hygiene," by J. T. Reeve, M.D., Secretary State Board of Health of Wisconsin; "Remarks on the Classification of Diseases," by Henry B. Baker, M.D., Secretary of the Michigan State Board of Health; "Meteorological Observations as Respects Disease Prevalence," by Professor Payne, Director of Observatory, Northfield, Minn.; "Some Personal Observations on Yellow Fever and its Habitudes as Opposed to the Fallacies and Dangers of Personal Quarantine," by A. N. Bell, M.D., Brooklyn, N. Y.

THE CHAIR OF ANATOMY at the College of Physicians and Surgeons, made vacant by the death of Dr. Sabine, has been filled by the appointment of Dr. R. J. Hall. Dr. Charles McBurney has been made Adjunct Lecturer on Surgery.

BEQUEST TO A HOSPITAL.—The late John Guy Vassar bequeathed in his will, for the completion of the Vassar Brothers Hospital, $25,000, and $200,000 in securities is given to be a part of the permanent maintenance fund; $17,000 more is bequeathed to this institution with the condition that certain annuities be paid from it.

DR. O. W. WIGHT, a brother of Professor J. S. Wight, of this city, died in Detroit, Mich., aged sixty-five. He was a pioneer in sanitary work, a man of great literary as well as scientific ability. The immediate cause of his death, says the *American Lancet*, was typhoid fever. But on his return from his voyage around the world last spring he brought with him what he called Egyptian fever, contracted while in Africa. He has never since his return exhibited the vigor characteristic of him while health officer of Detroit. Besides, he closely confined himself to writing a book giving an account of his winding journey round the world. This book has just been given to the public, and to it we will direct attention another time. He was a man who would impress the casual observer as more than ordinary in his physical and mental make-up. His education was far beyond the average, his energy ceaseless, and the marvel has always been to us that, at the age of sixty years of uninterrupted health, he was willing to take the position of health officer of Detroit, at a salary of $3,000 per year.

THE DEATH OF DR. JOHN S. LYNCH, of Baltimore, is announced. Professor Lynch was one of the leading physicians and most successful teachers of Baltimore, and his death is widely lamented.

THE DOCTOR AT HOME.—A doctor's wife, says the *Boston Medical and Surgical Journal*, was not long since overheard telling her husband that he was pleasant everywhere save in his own family; and the doctor admitted that his good-nature was so exhausted in his daily visits to his patients that he was irritable when he reached his home. "Exactly how true the doctor's admission was in that particular instance," our contemporary continues, "it is impossible to say, but it seems as though in the ordinary course of a doctor's existence such a condition might often occur. Physicians certainly meet with many things in their daily rounds that try their tempers. Life is for most of them a constant study how to coax or compel obstinate or ignorant, perhaps silly or even insane, patients to follow the course thought to be for their good. All these troublesome individuals must be reasoned with or influenced by some means to do as they ought. To carry his point the doctor must keep his temper. He usually preserves an outward calm, but if he is naturally quick tempered it is often at the cost of an effort which is exhausting. After such a struggle he reaches home in a state of irritability combined with mental and physical weariness, and under such circumstances it is not easy to meet little home trials with patience." We regret to notice in our esteemed contemporary a vein of apology for the irritable doctor which is hardly justifiable. The physician has no right to exhaust his good humor abroad and bring only an irritable mind to the domestic hearth. The doctor is expected to be a Christian or a philosopher, or both; and, if he is either, he can find no justification for being cross to his wife, and good-natured to his patients. We have known this evening irritability, which is not a characteristic of doctors by any means, to be relieved by a cup of bouillon, a five o'clock tea, or even a buffet-indulgence of a stronger character. Some physicians claim that effervescing caffein, or a good draught containing some mineral acid, relieves the tired and overstrung nerves. At any rate, the resources of religion, philosophy, the lunch-counter, and the drug-store, are open for the relief of this sunset erythism that follows hard work.

STROPHANTHUS AS AN ANTIPYRETIC.—Strophanthus in large doses has been found by Martini (*Rev. des Sciences méd.*) to reduce the temperature for a time.

A HOT-AIR CONTROVERSY.—Dr. Louis Weigert, late of New York, now of Berlin, and Dr. Halter, are having a heated controversy as to priority regarding the discovery of the utility of hot-air in the treatment of phthisis; Dr. Halter is accused of having patented his apparatus, contrary to the medical ethics.

DEATH OF THE LARGEST WOMAN IN THE WORLD.—There died at Baltimore, on September 4th, a colored woman who weighed, it is stated, eight hundred and fifty pounds. If the figures are correct, the deceased was, in a physical sense, the greatest woman in the world, if not the greatest that ever lived. Even the famous Daniel Lambert only reached the comparatively ordinary weight of seven hundred and thirty pounds. We have no record of any man exceeding the supreme obesity of the Baltimore lady, with one exception. In the year 1798 the modest State of North Carolina became the birthplace of Mr. Miles Darden, who, in the course of years, reached the height of seven feet six inches, and the weight of over one thousand pounds. North Carolina has shown pride in her agricultural and political resources, but she has really never done historical justice to the Darden half-ton of obese humanity.

Society Reports.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, October 10, 1888.

W. P. Northrup, M.D., President, in the Chair.

Dr. T. H. Myers presented, on behalf of a candidate, a *small vesical calculus*, which was discovered by the cystoscope, dislodged, and subsequently passed per urethram.

Dr. T. Mitchell Prudden presented two candidate-specimens, the first showing some pieces of *iron wire perforating the stomach of a pig*, the second being one of *multiple abscesses of the liver.*

Dr. Hodenpyle presented some microscopical specimens prepared according to

WEIGERT'S CORRECTED METHOD FOR STAINING FIBRIN IN SECTIONS.

The method, which is described in detail in the *Fortschritte der Medicin*, vol. xviii., p. 693, 1888, is as follows: The sections are spread out on glass slides, dried with filter paper, stained for five minutes in gentian anilin water, and again dried with filter paper. They are then placed in Lugol's solution of iodine for from thirty to sixty seconds, and finally decolorized in a mixture of zylol one part, and anilin-oil two parts. They are mounted in balsam. The specimens should he hardened in alcohol. By this method the shreds of fibrin are stained a deep blue, all the other parts being decolorized. They show much better in the daytime than by artificial light.

Dr. Mary A. Dixon-Jones presented a series of seven specimens showing that

MISPLACEMENTS OF THE UTERUS

are in many instances due to and complicated by diseases of the uterine appendages.

All the patients gave a history of long suffering and sterility, and had been through the usual course of treatment with pessaries and other supports, but without relief. Operation disclosed the uselessness of such forms of treatment, as the pelvic organs were displaced and bound down by inflammatory exudates, and extensive disease of the ovaries and tubes coexisted. In some instances the ovaries were atrophied, in others enlarged, and in still others they were the seat of purulent degeneration. Pyosalpinx was also of frequent occurrence.

Laparotomy was successfully performed in all seven cases, and the patients have been free of pain since.

Dr. Van Santvoord presented a specimen of

RUPTURE OF THE ARCH OF THE AORTA.

The patient was a man, forty years of age, who was admitted to hospital for some cerebral trouble, of which no definite history could be obtained. It was thought that the affection was syphilitic in its origin, and the man was put upon appropriate treatment. Eight hours before death the patient became markedly cyanotic, and a murmur was heard which was supposed to indicate aortic trouble. At the autopsy the aortic valves were found to be unaffected. There was, however, an aneurism of the arch of the aorta, situated just above the valves, which had ruptured into the superior vena cava. The rent was about one-third of an inch in length. The cerebral lesion was found to consist in multiple spots of softening from vascular disease.

Dr. Van Gieson exhibited two slides showing specimens of

ACCESSORY PANCREAS IN THE WALL OF THE DUODENUM, SIMULATING A TUMOR.

One of the specimens formed a whitish nodule, about 8 x 4 mm. in diameter, situated in the musculosa of the duodenum of a new-born child, and projecting in the lumen of the gut. The nodule was composed of lobuli of the pancreas lying between the mucosa and serosa.

The second specimen was taken from a man aged thirty-five. There was a white flattened mass, 1½ ctm. by 6 mm. in diameter, in the wall of the duodenum, through which the common bile-duct passed. The mass consisted of lobuli of the pancreas, lying between interlacing bands of the musculosa.

Dr. Ferguson had seen a similar case some time ago in St. Luke's Hospital. The supernumerary organ was about half an inch in thickness, and it was identical in structure with the true pancreas. The speaker had neglected to note whether there was an excretory duct present.

Dr. Prudden said that these cases were interesting in that there was danger of mistaking the glands for carcinomatous tumors, as they bore a very close resemblance, in gross appearance, to the latter when the sections were made in a certain direction. In the specimens presented there was no difficulty in recognizing the ducts as ducts, but if they had been cut in another direction the resemblance to that form of carcinoma which looks like adenoma would have been very striking.

The President said that he had been interested in the specimens for the very reason mentioned by Dr. Prudden, for he had seen one of them before, and at the first glance had pronounced it carcinoma.

Dr. H. M. Biggs presented a specimen showing

RUPTURE OF THE HEART,

which had occurred in a man seventy-four years of age. He was an inmate of the almshouse, and was working in the kitchen one day when he suddenly fell down, and died before the physician could reach him. At the autopsy it was found that a rupture of the anterior wall of the left ventricle had taken place. The tear was a ragged one, 6 or 7 mm. in length. The pericardium was distended with blood.

A second specimen presented was one removed from the body of a girl, showing

PRIMARY TUBERCULOSIS OF THE KIDNEY.

The other organs were free from disease, except the lungs, in which some recent miliary tubercles were found. Tuberculosis of the genito-urinary organs is not very uncommon, but it was rare, in the speaker's experience, to find it localized in the kidney.

Dr. Biggs also presented a specimen of

MULTIPLE GALL-STONES IN THE LIVER,

removed from the body of a man who had died in Bellevue Hospital. No history of the case had been obtainable. At the autopsy were found evidences of extensive fibro-serous peritonitis; there were also pleural adhesions and acute pericarditis. All through the liver the smaller bile-ducts were dilated, some forming cysts of considerable size and containing gall-stones. Small abscesses had formed on the upper surface of the liver and there were adhesions between this viscus and the diaphragm. There was one abscess in the left lobe, 3 ctm. in diameter, which, like the cysts, contained gall-stones.

There was also a smaller abscess in the right lobe. From one of these abscesses the inflammatory process had extended into the pericardium, and from the other into the pleural cavity. The gall-bladder contained no calculi, and the larger ducts were also free from them.

Dr. Prudden said that he had never seen a case in which the gall-stones in the liver were so numerous.

Dr. L. Emmett Holt presented the lungs of a child, nineteen months old, an inmate of the New York Infant Asylum, which showed

BRONCHO-PNEUMONIA AND PULMONARY ABSCESS COMPLICATING ULCERATIVE COLITIS.

The child was taken, on August 11th, with acute diarrhœal symptoms and high temperature. The fever subsided after four or five days, but the diarrhœa persisted, with variable severity. The movements were from four to six daily and varied in color from yellow to yellowish green and black, with much mucus but no blood. At times they were quite offensive. On September 11th the temperature again rose rapidly, reaching 104.8° F. It continued elevated until death, fluctuating between 100° and 103° F. The signs of commencing broncho-pneumonia were found at this time, first at the left base behind, then extending to the right base, and finally along the whole spine on the left side. No exacerbation of the diarrhœa accompanied these symptoms, the movements continuing about as above throughout the illness. The spleen was markedly enlarged, so that it could be felt an inch and a half below the ribs. The child emaciated rapidly, was exceedingly irritable, and it was only by the greatest patience that any physical examinations of the chest were made. She died, October 8th, having lost six pounds during the two months of her illness.

Autopsy, twenty hours after death. Brain: Pia œdematous; otherwise normal. Lungs: Adhesions over middle and lower lobes, mostly old and firm; similar adhesions over the whole left lung, behind and laterally. The breaking up of the adhesions opens, at the apex of the left lung, an abcess with ragged walls, containing about an ounce of thick, creamy pus, not fetid. Pus welled up in the trachea upon pressure, but it seemed rather doubtful whether a free communication with a bronchus had existed during life, as no pus to speak of was expectorated. The posterior part of the rest of the upper lobe and the whole lower lobe showed the usual changes of acute broncho-pneumonia. The same appearances were seen in the right lower lobe, posterior half, and a few scattered spots elsewhere. No small abscesses were present; bronchial glands much enlarged, not cheesy. Heart pale. Liver: Enlarged and quite fatty; weight, one pound two ounces. Spleen: Firm and adherent to abdominal wall, and about four times the usual size; weight one ounce six drachms. Kidneys: Enlarged; weight, one ounce two drachms; very marked cloudy swelling. Stomach: Contained large firm curds, and showed small ecchymoses in mucous membrane, near pyloric end; otherwise, no gross changes. Intestine: Small intestine pale throughout; has a "washed out" appearance; villi distinct; Peyer's patches normal; intense congestion in the rectum and sigmoid flexure but only moderate in the rest of the large intestine; rectum markedly thickened; solitary follicles not much enlarged. In the transverse and descending colon and rectum are many irregular ulcers, the largest half an inch broad; for the most part they involve the mucous membrane only. In the transverse colon some go to the circular muscular coat. They are all old in appearance. Mesenteric glands were enlarged and pale; not cheesy. The association of broncho-pneumonia with entero-colitis was something very commonly met with. A process in the lung, such as shown in the specimen, was decidedly uncommon. It suggested, however, some possible connection between it and the intestinal lesion.

The ground had been taken by some that all the cases of broncho-pneumonia complicating intestinal disease were due to infection.

GENERAL MILIARY TUBERCULOSIS.

Dr. Holt also presented specimens from an infant thirteen weeks old, illustrating general tuberculosis with obscure symptoms. The child was premature, mother delicate, and grandfather tubercular. On admission in July the child weighed four pounds; two days before death its weight was five pounds six ounces. The mother had but little milk, and this deficiency was made up by malted milk.

Except a very large spleen and dyspeptic symptoms, as shown by occasional vomiting and abnormal stools, the child gave no evidence of disease beyond the fact that it did not thrive. There was no cough. During the last five days the temperature was kept at, and it never rose above, normal. It was occasionally subnormal, and this condition existed for twenty-four hours before death. The autopsy was made thirty-six hours after death.

The brain showed a few miliary tubercles, but no evidences of meningitis.

The lungs were closely studded with miliary tubercles throughout, and showed many minute cheesy nodules, but no large ones; no pleurisy, and not much broncho-pneumonia. Bronchial glands were enlarged, cheesy, and broken down.

The spleen was five times normal size, miliary tubercles were seen on its surface, and the whole organ was thickly studded with small cheesy nodules.

The mesenteric glands were large and cheesy, slight catarrhal changes were found throughout the intestinal tract, and in the ileum two or three minute ulcers, not connected with Peyer's patches, which were normal.

The case was of interest as showing how few symptoms even a wide-spread tubercular process often gives in a very young infant, and, secondly, in view of the great enlargement of the spleen. This symptom had been advanced by some recent writers as of a good deal of value in making a diagnosis of tuberculosis in infancy. The speaker, however, had found it a very untrustworthy symptom.

Dr. Van Santvoord said that in his experience the diagnosis of tuberculosis in young children was very difficult. The symptoms were very irregular, and there was often nothing upon which to base a certain diagnosis.

The President thought that there was no rule as to the relation between enlargement of the spleen and tuberculosis.

On motion, the lung shown by Dr. Holt was referred for examination to the Committee on Microscopy.

Dr. Frank Ferguson presented a specimen, showing the lesions of

ANGINA LUDOVICI,

removed from the body of a man thirty years of age, a native of Italy, married, and a laborer by occupation. He was admitted into New York Hospital on September 1, 1888. For five days previous to his admission he had noticed a swelling in the floor of his mouth, and a gradual stiffening of his jaws. He was, on admission, unable to move the inferior maxilla, and suffered great pain. He could give no cause for the swelling, but says it commenced opposite the angle of the lower jaw. He had much swelling and induration in the floor of the mouth, extending upon the outer side of the inferior maxilla as high as the alveolar margin. The anterior surface of the neck was also swollen and indurated down as far as the cricoid cartilage. There was distinct fluctuation beneath the floor of the mouth on the left side. Dark-colored offensive pus was drawn from this region by the aspirating needle. The mucous membrane was raised from the alveolar margin of the inferior maxilla, along the incisor and canine teeth behind, and as far back as the first molar on the left side. On the day of his admission an incision was made two and one-half inches in length, and running obliquely downward and backward from the hyoid bone to the inferior maxilla. This incision was carried through skin and superficial subcutaneous tissue, and opened into a cavity filled with several ounces of offensive pus. The cavity was irrigated daily with a solution of bichloride, 1 to 5,000, drainage-tubes inserted, and a bichloride dressing applied. On the night following his admission he had a chill, and complained of a difficulty in breathing and flatulency. He was very restless during this night. During the second, third, and fourth days in the hospital he perspired very profusely, his pulse was very rapid and weak, and his temperature rose from 101° F. to 104° F. On the fourth day he continued restless, frequently attempting to get out of bed. He was constantly and carefully stimulated, but he gradually sank and died, having a temperature just before death of 103° F.

At the autopsy there was found a pint of purulent fluid in the pericardium. Both layers of the pericardium were covered with recent lymph. There were numerous gangrenous cavities under the root of the tongue, which communicated with the wound along the lower border of the jaw, and from which pus extended downward through the mediastinum to the pericardium. The pus infiltrated the planes of fibrous tissue along the trachea, œsophagus, and great vessels in the neck. The other organs were normal. The fluid in the pericardium, as well as sections of the necrotic tissue beneath the tongue and lymph covering cardiac surface, were stained for micro-organism, and large colonies of micrococci were everywhere observed. They were the same as those ordinarily found in erysipelas.

Dr. Ferguson also presented a second specimen, showing

ACUTE MILIARY TUBERCULOSIS,

removed from the body of a boy, thirteen years of age, who was admitted into the New York Hospital on September 27, 1888. He gave no morbid family history, and had no bad habits. It was learned from his mother that he had been treated in St. Luke's Hospital, five years previous to his admission into this hospital, for hip joint disease, and was discharged cured. At the same time he suffered from a fractured patella, which also healed. He was in his usual health until two weeks before his admission, when he commenced to complain of pain in his left knee, varying with pain in left hip, for which no cause could be assigned; there was no swelling, heat, nor redness of the knee. About one week later he began to complain of a very severe general headache. At this time the pain seemed to leave his knee. He vomited, but not frequently or severely, his bowels were fairly regular, and there were no ocular symptoms. He had no chills, but suffered from high fever, with maximum elevation of temperature toward night. He had recently suffered from burning pain in his eyes, dryness of mouth and throat, and great thirst. He had a slight cough. He had epistaxis on two different occasions. His appetite was poor. On his admission he had no nausea nor vomiting, but his bowels were constipated. He complained of no abdominal pain or tenderness. He was very weak and suffered much from headache. A harsh, respiratory murmur was audible over both lungs, and the respiration was prolonged and accompanied by an occasional subcrepitant râle. His urine was alkaline, of amber color, specific gravity, 1.025, and had a trace of albumin, and microscopic examination showed some pus and blood-cells. On October 2d he commenced to develop a delirium of a low, muttering type; later, cephalalgia and subsultus tendinum, with well-marked restlessness; and later on he became entirely unconscious, having irregular convulsive movements of the muscles of the body, especially marked in the muscles of the arms and forearms. The pupils were both markedly dilated, the tongue was dry and brown in the centre, the abdomen was slightly distended and tympanitic, and the abdominal veins were enlarged and very prominent. There was some resistance to motion of the neck, but there was no pain nor tenderness. He vomited twice on the night of October 3d, and he had conjugate deviation of the eyes to the right, and his head was also turned to the same side. On the afternoon of the third he was quieter, sinking into a comatose condition, with the left side of the body motionless and apparently paralyzed. On the fourth he was perfectly comatose, the eyes were partially closed, but there was no strabismus and the pupils responded to light. On the sixth he seemed much improved, and was apparently conscious, making attempts to respond to directions given him, and he executed voluntary movements of the right side, but still showed much lethargy. The pulse had been getting gradually more rapid and feeble, but he remained in much the same condition as on the day before. There was a slight ulceration on the right cornea. On the sixth the coma gradually deepened, the temperature rose, the respiration became deep, labored, and rapid, and he continued to fail until 9.30 P.M., when he died. The temperature ranged from normal to 104 F., the pulse from normal to 160. and the respiration from 20 to 44 per minute. The urine, toward the close, had to be drawn with the catheter; it contained a trace of albumin, and responded to Ehrlich's test. It contained hyaline casts and a small quantity of pus. The bowels were persistently constipated. Ice was applied to the head, strophanthus and whiskey were given, and the patient was fed on peptonized milk.

Autopsy.—On inspection the body was found extremely emaciated. The rigor mortis was fairly well marked. The left leg was found two inches shorter than the right, and everted. The left hip-joint was anchylosed. There was a sinus in the upper third of the thigh, on its outer aspect, leading to the joint. The convolutions of the brain over the vertex were slightly flattened, and there was slight œdema of the pia mater. There was pus in the meshes of the pia mater covering the interpeduncular space, and the pia mater in the Sylvian fissures was studded with tubercles. The lateral ventricles were slightly dilated and filled with pale fluid. The floors of the ventricles were softened, as were also the corpus callosum and septum lucidum. On the right side there were a few young tubercles found in the ascending frontal convolution. The lungs, kidneys, spleen, and small intestines contained numerous small miliary tubercles, and there were very small tubercular ulcers in the ileum.

Dr. T. Mitchell Prudden presented a specimen of

CIRRHOSIS OF THE LIVER IN A RABBIT,

showing small nodular areas scattered throughout the liver-substance. There was nothing in the nature of the experiments to which the animal had been subjected to explain the occurrence of cirrhosis.

The Society then went into executive session.

Chromatic Asymmetry of the Iris.—It is well known that the iris may change color with the lapse of time, and pass, for instance, from blue to green. M. Féré directs attention to the color of the iris in the subjects of nervous disease. In lunatic asylums a blue iris is considered by the uninitiated to indicate insanity, but Féré's statistics do not lend any support to this idea. Asymmetry in the color of the irides, however, appears to show that its possessor belongs to the neuropathic class. It is very frequent in the insane, in epilepsy, and in hysteria; twenty-six per cent. of epileptics were found to have the sign, and about the same percentage obtained in hysterics. This iridic stigma, it is thought, may prove of practical value.

Gouty Urethritis.—Gouty urethritis is a disease the existence of which is not by any means universally admitted, but in a thesis published in Paris by M. Turbure some observations are made which claim attention. The discharge, he states, in gouty urethritis appears suddenly, and is abundant, and at first thick. Its color and nature are those of ordinary gonorrhœa at the acutest period. The pus is yellowish green, and it gradually diminishes in quantity and consistency until it disappears. The functional symptoms which accompany this urethritis are said to be almost negative. The inflammatory reaction is *nil*, there is no redness, and no swelling of the meatus. No pain is caused during micturition, and no burning sensation is noticeable in the urethra. In some cases, however, there is more or less complaint of pain. The prognosis is generally favorable, because, in the opinion of the author, general treatment is all that is necessary to bring about a good result.—*Medical Press*.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, November 1, 1888.

ABRAHAM JACOBI, M.D., PRESIDENT, IN THE CHAIR.

DR. J. LEWIS SMITH read a paper on

SUDDEN HEART FAILURE IN DIPHTHERIA.

Physicians who had had experience in the treatment of diphtheria had met cases in which symptoms, usually of sudden development, indicated dangerous heart failure, and death usually ensued, although the physician a few hours previously had made a favorable prognosis. The patient had perhaps been improving, when suddenly the scene changed; the pulse became feeble and abnormally slow or rapid—usually at first, slow and subsequently rapid—the respiration superficial, the surface pallid, and perhaps slightly cyanotic. In the more favorable cases the patient might rally by active stimulation, and perhaps eventually recover, or, after some hours, or a day or two of comparative comfort, succumb to a return of heart failure. Dr. Smith thought there was no other disease in which sudden, unforeseen, and fatal attacks of heart failure occurred so frequently as in diphtheria, and on this account, among others, physicians were frequently deceived in prognosis. A clear idea of the clinical history of heart failure could best be learned by a recital of typical cases. Such cases had doubtless occurred in the practice of physicians of experience in New York, but the author selected some from M. Cadet de Gassicourt because of the completeness of his records.

A child of two years entered Cadet de Gassicourt's service with diphtheritic pharyngitis of ten days' duration. The tonsils were large, still covered with pseudo-membrane, and the submaxillary glands were also enlarged. There were no laryngeal symptoms; no albumin in the urine. On the following day the velum and pharyngeal muscles were slightly paralyzed, the speech nasal, and deglutition moderately embarrassed. He was quiet the second night after admission, and also the next morning, but at 10 A.M. became chilly, the face and extremities slightly cyanotic; some dyspnœa. The pulse, at first abnormally slow, became rapid, the boy was agitated, groaned, and fell into a state of prostration. Suddenly, at 11 o'clock, he was violently agitated, uttering loud screams of distress, and fell back cyanotic and dead. The death-struggle did not occupy more than a minute. Two other similar cases were recited. Severe precordial, epigastric, and abdominal pain was present in some, if not most, cases of sudden heart failure in diphtheria, but these three patients were probably too young to call attention to it.

Gombault made a minute microscopic examination of the affected organs in these three cases. The point of special interest in the examination was the apparently healthy state of the pneumogastric and myocardium in the one case in which they were examined, and of the medulla oblongata in the three cases, while the gray matter of the spinal cord, which had no immediate nerve connection with the heart, showed marked degenerative changes.

Some other cases gave a somewhat different clinical history, the difference in one consisting in the fact that there was no agitation or moaning at the close of life, and that the heart-beat remained abnormally slow unless during the last moments; in another case paralysis of the velum and palate began on the third day of diphtheria, while the pharyngeal and nasal inflammations were in full activity; the urine was slightly albuminous. Three days later the muscles of the nucha and right shoulder were paralyzed. A few hours later the child complained of violent abdominal pains, followed by nausea and vomiting; the vomiting was partially relieved, but dyspnœa and a rapid heart-beat followed, and death resulted three hours after commencement of symptoms referable to heart failure. In some instances the loss of power in the heart occurred more gradually. Cadet de Gassicourt had met with one recovery to fourteen deaths after sudden and alarming symptoms of heart failure, and Sanné, Billard, and others had also reported recoveries.

Dr. Smith asked the questions: "What is the cause of sudden loss of power in the heart in diphtheria, occurring usually during apparent convalescence? Does it result from disease in the muscular structure of the heart, from thrombosis or ante-mortem clots in the cavities of the heart, or does it result from disease of the central organ of innervation—the medulla oblongata—or from disease and deficient conducting power in the nerves which control the heart's action—the pneumogastric—or in the branches which this nerve supplies to the heart as well as lungs and stomach, for these three organs appear, in most instances, to be affected simultaneously?"

Bouchut and Lagrange attributed sudden heart failure in diphtheria to endocarditis, and yet it was very seldom that a bruit or heart-signs indicative of endocarditis had been observed during life. Their belief was founded on the roughened appearance of the free edge of the mitral valve, and sometimes of the aortic valve; but Cadet de Gassicourt claimed that this was not of inflammatory origin, but an anatomical peculiarity originating during fœtal development, and Sanné, Parrot, and others had denied the existence of endocarditis as a cause of the heart failure. A more probable theory was granulo-fatty degeneration in the muscular fibres of the heart, consequent upon a prolonged and severe diphtheritic attack; but this could account only for a part of the cases, and not for the larger number of instances in which the weakening of the heart was sudden and during convalescence, at a period when the degenerative changes were not likely to occur. In most of the recorded cases the contractile power of the heart did not appear to have been notably weakened previously to the heart failure, as it probably would have been had degenerative changes in the myocardium been the sole or chief cause. Then in some typical cases the myocardium appeared normal.

Cardiac thrombosis had been regarded as a cause, but, as several writers had pointed out, the clots were identical in appearance and kind with those found in the heart after death from other diseases than diphtheria. There was every reason to believe they occurred during the death-struggle and were secondary to heart failure. French writers generally still referred to Dr. Beverley Robinson's thesis of 1871, in support of the view that death was due to heart-clot.

In searching for a cause of sudden heart failure in diphtheria we should bear in mind the fact that, as a rule, in typical cases it was preceded by palatal, and often multiple paralysis. The paralysis had continued for a time, extending perhaps from one group of muscles to another, when suddenly the heart passed under some powerful influence which restricted and overpowered its action. The theory of deficient innervation, or true cardiac paralysis, appeared most tenable, and applicable to the largest number of cases. This theory also afforded an explanation of the occurrence of concomitant symptoms in cases of sudden heart failure, such as vomiting, epigastric pain, dyspnœa, or irregular respiration, for the heart derived its innervation from the same source as the lungs and stomach, *i.e.*, through the pneumogastric. In classifying the forms of diphtheritic paralysis he felt satisfied in making a distinct class having the designation, cardiac paralysis, or to anglicize a French expression, cardio-pulmonary paralysis.

Speaking of etiology, the author said that what was true with reference to the cause and nature of palatal and multiple paralyses, and even of abolition of the tendon reflexes, was probably also true of cardiac paralysis. The theory which was most strongly advocated, and which appeared to be accepted by a large proportion of specialists in nervous diseases, under the lead of Charcot, was that diphtheritic paralysis resulted from a peripheral neuritis. Others, observing central lesions in the nervous system, had inferred they had an important share in the production of the paralysis.

Objections to these explanations were the following:

1. Cases occurred in which a carefully conducted microscopic examination revealed an apparently normal state of the nerves supplying the paralyzed part, and also of that part of the cerebro-spinal axis from which the nerves arose.

2. Palatal paralysis sometimes occurred as early as the second or third day of diphtheria, and loss of the tendon reflexes as early as the first day, and it seemed improbable that a peripheral neuritis, or anatomical changes in the cerebro-spinal axis, had occurred at so early a date as to cause the paralysis.

3. In its commencement diphtheritic paralysis often exhibited what Trousseau designated mutability, suddenly shifting from one group of muscles to another. This mutability of the paralysis militated strongly against the view that it was caused by structural changes in the nervous system.

4. Where degenerative changes had been found in the peripheral nerves some of the fibres had remained intact. Would there be complete paralysis were this lesion the cause?

5. A clinical fact in opposition to the view that the lesion in the cerebro-spinal axis was the cause of the paralysis, had been alluded to by Dr. Suss and Dr. W. H. Thomson, namely, that the diphtheritic paralysis was frequently limited to a single branch of the nerve.

The theory relating to the etiology of diphtheria which was gaining ground was, that the specific germ acted only locally on the surface, and the systemic infection occurred through ptomaïnes, which were produced upon the surface by the agency of the microbes, and entered the system through the lymphatics and blood-vessels.

Treatment.—It was evident that the cardiac paralysis should be treated promptly and with the most active remedies. The patient should be as quiet as possible in bed, with the head low, and alcoholic stimulants administered at once. In sudden seizures hypodermic injections of brandy acted most promptly in sustaining the heart's action. Ammonia, camphor, musk, and the electrical current aided. The predigested beef preparations, peptonized milk, and other concentrated foods designed for those with feeble digestion, were useful. If the urgent symptoms were thus relieved, such remedies should afterward be used as had proved beneficial in other forms of diphtheritic paralysis. Iron, quinine in moderate doses, and alcoholic stimulants were indicated; the electric current was suggested by the nature of the attack. Strychnine was regarded by good observers as the most efficacious nerve stimulant.

THE PRESIDENT suggested that the paper raised the following points for discussion: Was the heart failure occurring early in the attack and that occurring at a late period identical, or had they a different cause? The author had spoken of cases with a slow pulse and others with a frequent pulse. Were they identical, or had they different causes? And, lastly, was the cause the same in cases preceding general paralysis and in those following general paralysis?

DR. A. L. LOOMIS was requested to open the discussion, but said he had seen comparatively little of heart failure in diphtheria; in fact, only two cases. In both the heart failure took place during convalescence, in one about the twentieth day after the commencement of diphtheria. In both death was instantaneous. In one the child, aged twelve, had attempted to rise from the sofa and fell back dead. The heart cavities were distended with a firmly organized blood clot, and the right cavity was much dilated; the walls were flabby and granulo-fatty. No autopsy was obtained in the other case.

He had supposed sudden heart failure in diphtheria was not always dependent on the same cause. When it occurred early in the disease he had supposed it depended on the diphtheritic poison, whatever that might be, and that it was a part of the history of the disease. It was not unlike sudden death from heart failure in typhus fever. He had rather yielded to the general opinion that the cause was a peripheral neuritis when heart failure occurred late in diphtheria, but he had no evidence to offer.

DR. CAILLÉ had held the view, during the first years of his practice, that children with diphtheria should be kept as much as possible in the fresh air, but he had changed this view, and now believed they should be kept in bed to prevent heart failure. A girl, ten years of age, had a diphtheritic deposit on both tonsils. She did not appear to be very sick, and he gave his usual order, to have her take moderate exercise out of doors. On the eighth day she developed paralysis of the velum; on the ninth, while walking slowly with her mother, she appeared suddenly to be in great distress, and had to be carried home and put to bed. He found her suffering from heart failure. She remained abed two months, and developed the following complications: Thrombosis of the right leg, then hemiplegia of the entire left side with aphasia, finally pneumonia, subsequently acute nephritis with abundance of albumin in the urine and granular casts. She finally recovered, and was still alive, but had contractures on the left side, and showed atrophic disturbances. The girl had refused to take whiskey, and he attributed the heart failure to want of stimulants and to taking exercise. In one case he thought fatal heart failure was due to an error in diet.

He thought there would be few cases of heart failure in diphtheria if all patients were kept in bed, not permitted to commit errors in diet, and were sufficiently stimulated.

DR. BEVERLEY ROBINSON had at one time made many autopsies on children who had died of diphtheria, and had entertained rather definite opinions regarding heart failure in the acute stage. He had come in after Dr. Smith's paper had been read, and did not know whether it advanced proof against the view which he yet held, that heart failure, at least during the acute stage of diphtheria, was in the majority of instances dependent upon ante-mortem formation of clots in the heart, more particularly on the right side. Granulo-fatty degeneration of the heart muscle was frequently met in diphtheria, and was probably always present in some degree in heart failure during the acute stage. He had been unable to detect any lesions in the peripheral nerves. The color, the consistency, and the effects of the clot upon the valves of the heart had led him to believe it had been formed at a time when the heart still retained considerable vigor, and the clot seemed to be the immediate cause of death. Sometimes there was more or less bronche-pneumonia in such cases; he could not discover any changes in the nerves of the heart. Tincture of chloride of iron was very commonly givne in large doses to children with diphtheria, and he questioned whether it was not a cause of the formation of heart clots. At any rate it was not altogether good practice.

DR. J. H. FRUITNIGHT hardly thought heart clot, granulo-fatty degeneration of the cardiac muscle, or peripheral neuritis would account for the sudden death; but toxæmia from ptomaïnes seemed a very plausible explanation. He differed from Dr. Robinson regarding tincture of chloride of iron, and recommended its use. If this were a cause, heart clot should be much more frequent.

DR. SEIBERT thought there were two classes of heart failure. He recited a case illustrating the first class, in which the heart failure or collapse was due to the direct action of the diphtheritic poison on the central nervous system in the beginning of the disease. The other class was in persons who had suffered from gangrenous condition at the seat of the false membrane, and death took place suddenly upon some exertion, as an attempt to rise in bed, and was undoubtedly due to pathological changes in the heart.

DR. DESSAU believed that sudden death in diphtheria might be due to different causes; in the acute stage particularly, to heart clot; and in some cases, it would seem, to paralysis of the pneumogastric nerve. Regarding treatment by strychnine, he thought this was a dangerous remedy to administer to children, as they were very susceptible to its influence. He had reason to believe that in one case it was the cause of death, although given in not very large doses.

DR. LOOMIS said, regarding heart clot, that he did not believe it was possible in these cases to have heart clot until after heart failure, in which event the cause of death was the heart failure and not the clot. In true cardiac thrombosis, in the condition in which there was interlacing of the fibres with the chordæ tendineæ and valves, with decoloration of the clot, and possible occlusion of the large vessels, there had been a degree of heart failure for quite a time preceding death. He could hardly conceive how any remedial agent could increase the coagulability of the blood beyond the point reached in most inflammatory diseases. It was not because the blood coagulated more easily, although that might have a little influence, but it was because of retardation of the blood-current, which allowed thrombosis either of the blood-vessels or heart.

DR. ROBINSON replied that the heart clot differed from that commonly found after death from other diseases; it was absolutely fibrinous, often in layers, and had certainly lain in the heart a goodly period previous to death. Its presence was not pointed to by any symptoms during life. Experimentation had shown that clots might form in the heart when there had been no change in the structure of the organ.

THE PRESIDENT, before discussing the paper, gave notice of the anniversary meeting to be held November 15th, which he hoped would be largely attended by the profession and public. Regarding sudden death in diphtheria, when there was fatty degeneration in the heart, it was sufficient to account for death. Patients with this disease and others which left them in a weak state, were liable to sudden death from anæmia of the brain. One condition might be mistaken for heart failure in the later stages of diphtheria, namely, paralysis of the respiratory organs. There was dyspnœa, with necessarily frequent and shallow respirations, and as there was frequency of heart beat we might mistake it for heart failure. He recommended electricity, short sessions frequently repeated; also strychnine, which should not be relied upon by internal administration alone, but by hypodermic injection. Since the majority of cases of heart failure in diphtheria died, all things possible should be done to prevent its occurrence. Save the strength of the patient, add to it by correct feeding, by tonics so-called, employ stimulants, particularly alcohol. The most courageous gave usually too little alcohol in diphtheria.

DR. SMITH recapitulated some facts contained in his paper. Since in a very considerable number of typical cases of death from heart failure in diphtheria there were symptoms referable to the stomach, lungs, and heart, the inference was that the pneumogastric was involved. Then many patients could be rallied by stimulants, go on some hours or days and have a recurrence; did that fact not contra-indicate heart clot? Again, in many cases there was multiple paralysis, which seemed to point to a similar cause for the heart failure.

SECTION IN OBSTETRICS AND GYNÆCOLOGY.

Stated Meeting, October 25, 1888.

JOSEPH E. JANVRIN, M.D., CHAIRMAN.

DR. CHARLES CARROLL LEE read a paper on

THE VALUE OF HYSTERORAPHY AS A PRIMARY OR CONSECUTIVE OPERATION IN UTERINE DISPLACEMENTS.

A comparatively new surgical procedure, which, on the one hand, was not very difficult to perform, and, on the other, afforded certain relief in cases hitherto intractable, was of sufficient interest to justify the paper. The name hysteroraphy, which signified suturing the uterus, had been given by Dr. Howard H. Kelly to the process of sewing the displaced uterus to the anterior wall of the abdomen. For ten years, or more, efforts had been made to fasten the uterus to the abdominal wall, to retain it in a corrected position supplementary to laparotomy done for other purposes. Dr. Lee here reviewed the subject from a historical standpoint, making some use of Dr. Kelly's article published in 1887. As far as he was informed, the first person who urged resort to hysteroraphy as a primary operation, for the sole purpose of securing in position an otherwise intractably displaced uterus, was Professor Olshausen, who discussed the subject in a paper in 1886. Sänger adopted the procedure, and in comparing hysteroraphy with Alexander's operation, condemned the latter

Dr. Lee then gave the histories of six cases in which he had performed primary hysteroraphy. The operation had been done so frequently, secondary to laparotomy for other purposes, that he did not refer to his experience with such cases. In all the six there was retroversion of the uterus, with strong adhesions and attendant symptoms which all other means had failed to relieve. Laparotomy was performed and the adhesions broken up, although usually with much difficulty, and the uterus was fastened by suture to the anterior abdominal wall. In one case the uterine appendages had previously been removed, but the patient continued to menstruate and to suffer severe pain. Finally he again performed laparotomy, broke up perimetric adhesion, fastened the uterus to the abdominal wall, and there had been relief, although the final result could not be stated, the operation having been done the present month. In one instance the operation failed to give relief.

Although the operation was sometimes difficult of performance, yet it was certainly less dangerous than extirpation of the uterine appendages or a morbid growth, and it often gave relief from as severe symptoms. It was indicated in retroflexion of the uterus with fixation, great suffering which finally ruined the health, where pessaries were not borne, and if borne had no effect. Unless it should be supplanted by the massage and gymnastics practised by Brandt, hysteroraphy would be a great blessing to many patients. He had not practised Brandt's method, but he had felt sceptical regarding its claims. Regarding the relative value of hysteroraphy and Alexander's operation, he thought it useless to speak, for they were indicated in different classes of cases. If there were no adhesions, no fixation of the displaced uterus, even the most enterprising laparotomist would hesitate to advise hysteroraphy, while it had been claimed that in only such cases was Alexander's operation to be performed.

Regarding the steps in the operation, Dr. Lee said that after a number of experiments he had concluded the sutures should not be passed through the fundus uteri, which was often excessively vascular, but through the proximal end or edge of the broad ligament, so as to encircle the round ligament, and above, not only through the parietal peritoneum, but through the supra peritoneal fat; for otherwise they were liable to tear through and allow the womb to fall back again While silkworm gut answered well if previously soaked to make it flexible, the very best material was fine Chinese twisted silk rendered aseptic. Catgut was inadmissible from liability to rapid absorption, and silver wire was much more likely to tear the broad ligaments. The aim was to have the ligature remain and become encysted. In separating the adhesions, the fingers alone were to be used, and the adhesions about the ends of the broad ligament were to be torn through first, and when the uterus was drawn up one could better distinguish the utero-sacral ligaments from adhesions. The operation was only to be done with all antiseptic precautions. The subsequent treatment was like that in other laparotomies. Thus far he believed no death from hysteroraphy had been recorded.

DR. HOWARD KELLY, of Philadelphia, present by invitation, said that since writing his first paper he had learned that Käberle, of Strasburg, was the first to perform hysterorapby, it being in March, 1869, an account of the operation being published in 1877. Then followed Olshausen, then Kelly, then Sänger. The operation was suitable to cases of retroflexion in which Alexander's operation was contra-indicated. He took occasion to state that his former objections to Alexander's operation were only theoretical, and the paper of Dr. Mundé seemed to show that it had a legitimate field. The method of massage and gymnastics practised by Brandt would not do away with hysterorapby, but simply limit its applicability. Dr. Kelly also spoke of the importance of doing hysterorapby in connection with laparotomy for other purposes, since in these cases it was impossible to say just how much the symptoms were due to the disease or to the displaced uterus.

There were two classes of cases, those in which the adhesive bands were light and easily broken up, and those in which they were very tenacious, making of the operation one of the most difficult in abdominal surgery. In the first class the uterus was likely to be fixed at an acute angle, was large and vascular. The relief which the operation afforded in these cases was very striking. When the patient had been suffering a long time from displacement, had usually passed thirty-five years of age, had a short vagina, a small uterus bound firmly down by adhesions, it was a question whether the operation would prove useful.

In performing hysterorapby the abdominal incision should be made much lower than in ordinary laparotomy; it should come close down to the pubes, in order to be able to attach the uterus as near the pubes as possible, and prevent the intestines from entering between the pubes and uterus and developing ileus. Sänger used four sutures, passing them through the broad ligament. Dr. Kelly used at most two. The method of attachment varied with different operators. Sometimes the broad ligament was spread out and very vascular, in which case Dr. Kelly thought it best to pick it up, and pass the sutures where no blood-vessels were apparent which might be wounded. He had sutured the broad ligament, also the tube, and had in two cases reached over the uterus and attached the ovarian ligament, which was of advantage when the ovary was displaced.

Dr. Kelly regretted to record the first death after hysterorapby. He wounded the vessels in the broad ligament, and as a matter of safety, followed the example of Sänger and sutured the vessels to stop hemorrhage. The operation was somewhat prolonged, and he put in a drainage-tube. The patient got along very well for a time, and he took out the tube, but adhesions formed to the intestine along its track which caused ileus and death. He had the records of over ninety cases of hysterorapby without one other death.

Dr. P. F. Mundé had attempted hysterorapby in only one case, in which he found the uterine adhesions so strong that he abandoned the operation. He thought Dr. Lee had clearly shown the field of the operation, while that of Alexander was entirely different, for in the latter uterine adhesions constituted a positive contra-indication.

Dr. H. J. Boldt considered hysterorapby a very valuable operation in properly selected cases, but he was positive that the primary operation could be much restricted by the employment of Brandt's method of gymnastics and massage, which should first be given a fair trial. A prerequisite to Brandt's method was a correct diagnosis. Dr. Boldt's method of doing hysterorapby at present was to make the abdominal incision as small as the case would permit, tear up the adhesions with the index-finger, then pass his guarded tenaculum behind the uterus, slide the guard off the sharp hook, at the same time introducing the latter into the muscularis of the uterus, which he brought to the surface of the abdominal wound; while his assistant held the womb, he passed a silkworm gut through the entire thickness of the abdominal wall, and then through the fundus uteri just beneath the peritoneal covering.

If circumstances required him to operate on a large, soft uterus, he would prefer to pass the sutures through and around the round ligaments.

As to ventral fixation at a consecutive operation in uterine displacement, he would regard any operation as incomplete without it when once the abdomen was open.

Dr. Coe spoke as follows: In considering the indications for this operation, we must not forget that it was undoubtedly performed originally as an adjunct to oöphorectomy. A review of the papers by Olshausen, Leopold, Sänger, and other German writers, will show that they, like every other laparotomist, had encountered cases in which pain and hemorrhage were not relieved after removal of the appendages, when the uterus remained retro-displaced and adherent. Hence their attempt to avoid this failure by replacing the uterus at the time of the operation. Long before I had heard of ventro-fixation, I was interested in seeking for the cause of persistent pain after oöphorectomy, and had noted that it was commonly associated with retroflexion and fixation of the uterus; so that, when I observed this condition at the operating-table, I was able to predict with considerable certainty that the patient would not be entirely relieved. In fact, I would not limit the probability of failure to cases of laparotomy. We all know that as long as the uterus is adherent in a position of retroflexion, minor operations upon the organ, such as curetting or repair of a lacerated cervix, are only of partial and temporary benefit, while operations on the pelvic floor are worse than useless. At the risk of being severely criticised for making such a sweeping statement, I would thus summarize: It is doubtful if pelvic pain and hemorrhage can be relieved by operative interference, so long as the uterus is fixed in the malpositions referred to. It is assumed that the adhesions are of the firm fundal variety, which resist pressure and stretching by both the tampon and massage. My views regarding the futility of tamponing in such cases were expressed in a paper read before the Obstetrical Society, two years ago. When the uterus cannot be replaced before operation, this must be done at the time; hence the inference that ventro-fixation is simply the natural course to follow under the circumstances. It seems to me that there is no need of making a sharp distinction between what the reader had denominated the "primary" and "consecutive" operations, since we can never decide positively whether we shall remove the appendages or not until the abdomen has been opened. The difference really exists in the mind of the operator; if he performs the operation with the express purpose of freeing the adherent uterus, then it is primary; if this measure occurs to him as an after-thought, subsequent to removal of the tubes and ovaries, it is secondary. Understanding the difference of the terms thus, I have had two cases of primary hysterorapby, in one of which I introduced a temporary, in the other permanent uterine sutures. The appendages were removed in both instances, and I think that this will usually be found to be the wiser course, since tubes and ovaries that have long been buried in adhesions seldom present such anatomical integrity that they can be left with safety. Both patients had been great sufferers, and had been under constant treatment for two or three years. In both, the relief was immediate and permanent, although in the case of the first patient (who was operated upon nearly a year ago), the uterus has, in consequence of severe muscular efforts, been detached from the anterior abdominal wall and is again retroverted, but small and movable, while there is no tender spot in the pelvis. The second patient has not been under observation sufficiently long to allow of a positive inference in regard to the permanence of the cure.

I am firmly convinced of the value of the procedure in all cases of laparotomy in which the uterus is retro-displaced and adherent, although while I agree with Dr. Boldt that such a laparotomy is imperfect without an attempt to restore the organ to its normal position, it is not possible to do so in every case, even after the adhesions have been separated, as the shortened utero-sacral ligaments sometimes do not allow the uterus to be elevated sufficiently to suture it to the abdominal wall. Under these circumstances the operator will be greatly aided if an assistant lifts the organ with two fingers introduced into the vagina.

I believe that the operation has a future, and that although it may sometimes fail from a mechanical standpoint, the result will be equally satisfactory as in the case which I reported, when the uterus dropped backward, but not until the raw surfaces had healed and the organ was atrophied, so that the displacement no longer gives rise to the former distressing symptoms.

Dr. W. Gill Wylie thought this or a similar operation justifiable, although he did not regard displacement of the womb as of so much importance as some gynæcologists did. It had been the tendency to look upon displacements of the uterus as a disease rather than as a complication, and the same was true of uterine adhesions. It was his belief that in many cases in which Alexander's operation had been performed, a cure could have been effected by much simpler means. The same fact promised to prove true of hysteroraphy. In many cases, retroversion and fixation were unaccompanied by marked symptoms, and the women bore children. Suitable treatment of the subinvolution would often result in disappearance of adhesions. He thought the suggestion to attach the uterus to the abdominal wall in the course of a laparotomy was first made by Dr. J. Marion Sims, about twenty years ago. He did not approve of passing the needle and suture through the uterine wall, since the attachment could be secured by a much simpler method. Dr. Wylie had always practised breaking up the adhesions of the uterus when doing laparotomy, and in seven cases he had secured the anteversion of the organ by shortening the round ligaments within the abdomen. In three cases he opened the abdomen for this purpose alone. He took up a loop in the round ligaments, did not ligate them sufficiently tight to destroy vitality, but simply to create plastic adhesions after scraping the peritoneal coat. The result was much like that attending hysterorаphy.

Dr. Dudley had not done the operation, but he could not conceive how the sutures could retain the uterus against the abdominal walls in the face of such mechanical resistance.

Dr. Buckmaster spoke of the benefit of the vaginal tampon and massage.

Dr. E. C. Wendt added two cases to Dr. Kelly's list, being those at which he assisted Dr. Wido, of Freiburg, to do the operation. The indication for the operation in one case was different from those given to-night, it being a case of extreme mobility of the uterus in a primipara. The other was a case of prolapsus of a large, heavy uterus which could not be kept up by other means. Up to the time of his departure, the operation had been successful in both cases.

Dr. Lee replied to Dr. Dudley by saying that in his cases the uterus had remained in its new position, was fairly movable, and the patients had been relieved of pain. He had never dragged on, or tied the sutures so tightly that the uterus was immovable.

The Section then continued the discussion on papers read at the last stated meeting by Drs. Buckmaster and Hawley, on the relative value of electricity and primary laparotomy in extra-uterine pregnancy.

Drs. Buckmaster, Rockwell, and Malcolm McLane testified to the value of destroying the fœtus by electricity; while Dr. Hawley and the Chairman, as laparotomists, preferred to remove the fœtus through an abdominal incision, and thus get rid of a foreign body which might cause sepsis.

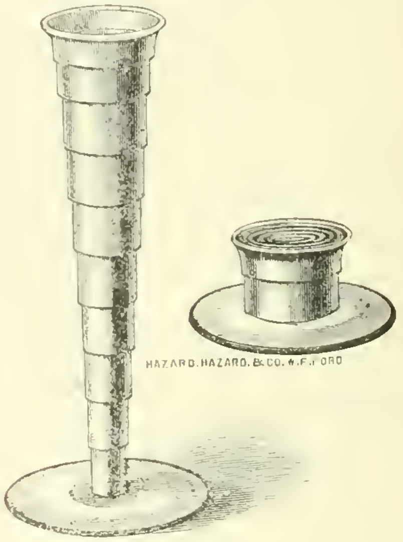
New Instruments.

A NEW POCKET STETHOSCOPE.

By D. M. CAMMANN, M.D.,

NEW YORK.

Laënnec's monaural stethoscope was a foot in length, with thick walls, and was cumbersome and heavy to carry. The stethoscopes of our day are rarely more than six inches long, with thin walls, and are light and comparatively easy to carry. All of those at present in use, however, are somewhat of a nuisance to take with us from place to place. The pocket stethoscope, the cuts of which are seen below, is offered to the profession, in the belief that it is more compact and easily carried than any at present in the market. The one cut shows it open and ready for use, in the other it is closed. It works on the principle of the telescope, or of the folding drinking-cup, so commonly used by travellers. It has nine joints. To the joint at one extremity is attached the ear piece, and at the other extremity the free end of the joint is curled, and forms the chest piece. When it is closed it is a compact mass, which can readily be kept in the vest or coat pocket. When opened it is so arranged, by a series of grooves on the outsides of the inside joints, and a series of projections on the insides of the outer joints fitting into these grooves, that by giving a turn to the joints the stethoscope is locked, and there is no chance of its collapsing when in use. The diameter of the aural end is one inch and seven eighths, and the length of each joint is three-fourths of an inch, and these are the dimensions of the instrument when closed. When open it is about six inches long. It is made of metal, and conveys sound in a very satisfactory manner.



I am much indebted to Mr. Ford, of Hazard, Hazard & Co., for carrying out my ideas, and from him the instrument may be obtained.

19 East Thirty-third Street.

A Fatal Case of camphor-poisoning is reported in the *Australian Medical Journal*. The patient was in the habit of nibbling at the drug, and carried it in her pocket. Nothing distinctive was discovered at the autopsy except a slight cerebral congestion. The quantity of camphor found in the stomach was very small.

He Missed the Mark.—Young physician (to patient): "What you need is exercise, sir. You should walk more." Patient (reaching for his pocket-book): "How much, young man? I was walking all last night with the baby."

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from October 28 to November 3, 1888.

BAILY, ELISH J., Colonel and Surgeon, and JOHN J. COCHRAN, Captain and Assistant Surgeon. Detailedf or duty on Army Retiring Board, to meet at San Francisco, Cal., for the examination of such officers as may be ordered before it. Par. 3, S. O. 253, A. G. O., Washington, October 30, 1888.

GLENNAN, JAMES D., and BRADLEY, ALFRED E. Appointed Assistant Surgeons, with rank of first lieutenants, to rank from October 29, 1888.

NORRIS, BASIL, Lieutenant-Colonel and Surgeon. Will be relieved from duty in the Department of the Columbia by the commanding general of that department, and will report in person, on or before November 14 1888, to the Commanding General, Division of the Pacific, for duty as medical director of that division, and of the Department of California. Par. 14, S. O. 255, A. G. O., Washington, November 1, 1888.

VOLLUM, EDWARD P., Lieutenant-Colonel and Surgeon. By direction of the Secretary of War, on being relieved from duty as Medical Director, Department of Texas, by Lieutenant Colonel Joseph C. Baily, assistant medical purveyor, under War Department order, dated October 31, 1888, S. O. 255, A. G. O., will repair to New York City, assume the duties of acting assistant medical purveyor, and take charge of the medical purveying department at that place. Par. 2, S. O. 255, A. G. O., Washington, November, 1888.

ALEXANDER, CHARLES T., Lieutenant-Colonel and Surgeon, is relieved from further duty in the Department of Dakota, and will report in person to the Commanding General, Department of the Columbia, for duty as medical director of that department. Par. 14, S. O. 255, A. G. O., Washington, November 1, 1888.

BAILY, JOSEPH C., Lieutenant-Colonel and Assistant Medical Purveyor, is, at his own request, relieved from the charge of the Medical Purveying Depot in New York City, and is, by direction of the President, under the provisions of the Act of Congress, approved June 23, 1874, assigned to duty as surgeon in the Medical Department. He will report in person to the Commanding General, Department of Texas, for assignment to duty as medical director of that department, to relieve Lieutenant-Colonel E. P. Vollum, surgeon. Par. 1, S. O. 255, A. G. O., Washington, November 1, 1888.

WEISEL, DANIEL, Captain and Assistant Surgeon. Died at Fort Sill, Ind. Ter., October 30, 1888.

STRONG, NORTON, Captain and Assistant Surgeon. By direction of the Secretary of War, relieved from duty in the Department of Arizona, and to report in person to the commanding officer, Fort Schuyler, New York, for duty at that post, and by letter to the Commanding General, Division of the Atlantic. Par. 4, S. O. 255, A. G. O., Washington, November 1, 1888.

ARTHUR, WILLIAM H., Assistant Surgeon. By direction of the Secretary of War, relieved from duty at Fort Bowie, Ariz., and to report in person to the commanding officer, Fort Bayard, N. M., for duty at that post. Par. 21, S. O. 250, A. G. O., Washington, D. C. October 26, 1888.

OWEN, W. O., JR., Captain and Assistant Surgeon, Fort Leavenworth, Kan., will proceed at once to Fort Sill, Ind. Ter., and report to the commanding officer for temporary duty at that post. Headquarters, Department of the Missouri, S. O. 133, Par. 1, Fort Leavenworth, Kan., October 30, 1888.

GLENNAN, JAMES D., First Lieutenant and Assistant Surgeon, recently appointed by direction of the Secretary of War, will repair from this city to Willet's Point, N. Y., and report in person to the commanding officer of that post for duty. Par. 3, S. O. 255, A. G. O., Washington, November 1, 1888.

Official List of Changes in the Medical Corps of the United States Navy for the week ending November 3, 1888.

GIHON, A. L., Medical Director Ordered to Naval Hospital, Brooklyn, N. Y.

TAYLOR, JOHN Y., Medical Director. Detached from Naval Hospital, New York, and ordered to Examining Board.

HUDSON, ADRIAN, Medical Inspector. Promoted to be Medical Director.

BRADLEY, MICHAEL, Medical Inspector. Promoted to be Medical Director.

BATES, NEWTON L., Medical Inspector. Promoted to be Medical Director.

WOOLVERTON, T., Surgeon. Promoted to be Medical Inspector.

WHITE, C. H., Surgeon. Promoted to be Medical Inspector.

WOODS, G. W., Surgeon. Promoted to be Medical Inspector.

DUBOIS, F. L., Surgeon. Promoted to be Medical Inspector.

COOKE, G. H., Surgeon. Promoted to be Medical Inspector.

WELLS, HOWARD, Passed Assistant Surgeon. Promoted to be Surgeon.

BERTOLETTE, D. N., Passed Assistant Surgeon. Promoted to be Surgeon.

GAINES, J. H., Passed Assistant Surgeon. Promoted to be Surgeon.

DEER, EZRA Z., Passed Assistant Surgeon. Promoted to be Surgeon.

STEPHENSON, F. B., Passed Assistant Surgeon. Promoted to be Surgeon.

THE ORIGIN OF DIPHTHERIA FROM ANIMALS.—It has been known for some years that birds and poultry are subject to a disease which corresponds to what in the human being is known as diphtheria. Several observers have gone a step further, and have endeavored to show that the disease is capable of transmission from animals to human beings. Last year Dr. Turner drew up an interesting report bearing on this alleged transmissibility, and he adduced a large number of observations which seemed to indicate a connection between a diphtheritic affection, not only in fowls, but in rabbits and cats, and a similar affection in man. The report comprised several instances in which the "strangles" in horses appeared to give rise to a like train of symptoms. In a thesis by Dr. Menzie, the transmission of the disease from animals to man is attributed to the dejections of the former. Diphtheritic affections among fowls are very common in Italy, and he quotes an instance in which four out of the five children of a medical man were attacked and died. In this case he incriminates the thatched roof, which was inhabited by colonies of fowls, geese, pigeons, etc. The dejections of these animals, washed off by the rain, found their way into the cistern or well from which the supply of drinking-water was drawn.—*Medical Press and Circular.*

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending November 3, 1888:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	40	5
Scarlet fever	104	20
Cerebro-spinal meningitis	3	2
Measles	135	6
Diphtheria	105	38
Small-pox	2	0
Yellow fever	0	0
Cholera	0	0

ELASTIC LIGATURES TO THE LIMBS FOR INTERNAL HEMORRHAGES.—As a result of experiments of two years' duration, Dr. E. Haffter, of Frauenfeld, highly recommends (*Correspondenz-Blatt für Schweizer Aerzte*, August 15, 1888, p. 515) the application of elastic ligatures to the limbs as an excellent substitute for venesection in cases of pulmonary congestion, venous hyperæmia of internal organs, hæmoptysis, certain cardiac diseases, etc. The extremities must be encircled at their base with sufficient tightness, if possible, to arrest the venous, without interfering with the arterial, circulation. The constriction—provided it is properly applied—is said to be safely borne for a very prolonged period. It is best to employ for the purpose a black rubber tubing, as thick as a lead-pencil. A similar procedure is warmly recommended by Dr. L. M. Sweetnam, of Toronto, in surgical operations of every kind. (See the *New York Medical Journal* of December 17, 1887.).—*British Medical Journal.*

DEATH FROM SWALLOWING BICHROMATE OF POTASSIUM.—A correspondent of the *British Medical Journal* reports the following case: H. McC——, aged forty-six, a notorious drunkard, during a drinking bout obtained one ounce of the salt "for a French polisher." She took the packet to her home, emptied its contents into a basin, filled up the basin with boiling water, allowed the crystals to dissolve, and drank off the contents of the basin. She was proceeding to refill the basin, so as to dissolve some remaining crystals, when her movements excited suspicion in those around her, and the basin was taken from her. Within five minutes she became unconscious. When first seen by us, twenty minutes after swallowing the liquid, she was still unconscious, and there was evidence on the furniture around her that she had suffered vomiting and purging. There was extreme pallor, with perspiration; pulse small, thready, and irregular; respiration slow, irregular, and gasping. It is not common to say that the corrosive poisons have a specific action on any organ. It would seem that this salt has a specific action, and that on the respiratory centres. From the very first the respiratory movements were markedly affected, sometimes a quarter of a minute intervening between the gasping respiratory acts, and respiration ceased fully a minute and three-quarters before the cardiac movements. An interesting point is the rapid action of the poison, in this case the patient being dead within forty minutes after taking the draught. Unfortunately a post-mortem examination was not obtainable.

EDUCATION IN RELATION TO HEALTH.—Dr. D. Clark, Superintendent of Toronto Asylum for the Insane, concludes an article on the subject as follows: "Were I to formulate the prominent natural features of the mind which need education, I would say: Quality (tone), quantity (power), tension (endurance), variety (scope), control (habit). These are given to us as a legacy, and to no two alike, but proper training increases them to a wonderful degree, if guided with wisdom and discretion. Education should be conducted somewhat as follows: 1. No teaching beyond object-lessons up to six years of age. 2. Object-lessons with reading and writing up to nine years of age. 3. Reading, writing, arithmetic in its four primary divisions, and geography, up to twelve years of age. 4. The preceding, with history and primary arithmetic and grammar, up to fifteen years. 5. From this age such studies as will assist the girl in feminine duties, and the boy to some definite employment or profession. 6. No studies in the evening until after fifteen years of age. 7. Three hours daily of school-time up to nine years of age, four hours to twelve, and six hours until fifteen years of age. 8. After fifteen years of age studies to be intermingled with congenial and useful mechanical work. This to apply to both sexes."—*Journal of Insanity.*

THE PHYSIOLOGY OF THEATRICAL EMOTION.—The innervation of the muscles which govern facial expression is, under ordinary circumstances, so intimately connected with certain psychological conditions that the two go hand-in-hand, more or less independently of the will. If anger be the dominant feeling for the time being, the face reflects that condition by the contraction of certain muscles which we have learned to associate with an angry mind both in ourselves and others. If, on the other hand, we voluntarily impart an angry expression to the face, the thoughts immediately become tinged with the sentiment of which the features bear the impress. It is only by long practice that we are enabled to intervene between the psychological and the muscular (or vascular) conditions. Our social education accustoms us, from infancy upward, to the exercise of some sort of control over the exhibition of the emotions, and to the well-trained individual it is comparatively easy to prevent his face divulging his thoughts and feelings. In the same way actors gradually become enabled to "tear a passion to very tatters" without showing the emotion to which their mimicry gives rise in the onlookers. An actor who really wept or who really laughed would be as little fitted for his task as a medical man who really experienced the sympathy which his speech and manners are intended to convey. Not that there is anything hypocritical in either case, but both have acquired the ability to disassociate the feeling from its normal manifestation. From a theatrical point of view it is surprising what education and practice can do toward converting into voluntary acts phenomena which in other people are utterly beyond the sphere of the will. It is reported that Baron, a disciple of Molière, could change from pallor to carnation at will, and many of the ladies who play the parts of *ingénues* can certainly command the rosy blush which is so becoming in injured innocence, and that too quite independently of the aid of carmine. Clowns have been known to acquire a wonderful mastery over the muscles of the external ear, which enabled them to move their pinnæ in a way which amused the populace as much as it interested the physiologist. The possession of such powers to a marked extent is, however, very rare, and is by no means common in or necessary to the histrionic art. It is far more difficult to acquire a face which can be made to blush at will than one which will not blush at all.—*Medical Press.*

CHANGES IN THE INSPIRED AIR IN PASSING THROUGH THE NOSE.—Dr. Kayster has repeated some experiments made by Aschenbrand, and has found that in an outside temperature of 50° F., the air in its passage through the nose is raised to 88°, and becomes saturated with moisture.

FORTY-THREE GALL-STONES PASSED BY A CHILD.—Dr. J. K. Cantrell reports, in the *International Medical and Surgical Synopsis* for August, 1888, the case of a child, two and one-half years old, who passed forty-three gall-stones, from the size of a pea to that of a marble, in the course of about two weeks.

The Medical Record

A CONTRIBUTION TO THE TREATMENT OF PYO-THORAX AND PYO-PNEUMO-THORAX BY THE SETON METHOD OF THROUGH DRAINAGE, WITH SOME CASES FROM PERSONAL EXPERIENCE BEARING ON THE MATTER.[1]

BY THOMAS E. SATTERTHWAITE, M.D.,

PROFESSOR OF PATHOLOGY AND GENERAL MEDICINE IN THE NEW YORK POST GRADUATE MEDICAL SCHOOL AND HOSPITAL.

AT the present time, when some of our best practitioners are urging more radical measures for the treatment of empyema, and when statistics prove that under these newer procedures the mortality has been largely diminished, I venture to lay before the profession my experience in the matter. While serving as an interne at the New York Hospital in 1867, I first had my attention directed to the large mortality from pyo-thorax in cases that fell under my care in the surgical wards. For it so happened that five penetrating wounds of the chest were admitted within a comparatively short space of time under my immediate observation, one-half of them dying of suppurating affections following their chest-wounds.

CASE I.—One instance in particular impressed itself remarkably on my mind. The patient was a policeman, C. T——, who was stabbed in the chest on November 4, 1867. The instrument was an ordinary butcher's knife, an inch in width. It had penetrated two and a half inches (as subsequently determined), entering the left side of the chest between the clavicle and the second rib, making an external wound two inches long. The patient was spitting blood when brought to the hospital. The wound was sealed tightly, but empyema appearing subsequently, it was opened. Pneumo-thorax was soon established, and the patient died some three weeks later of septic poisoning, numerous small abscesses having been found in both lungs at the post-mortem examination.

During my hospital service of twenty months, seven cases in all, of a somewhat similar nature, fell under my observation. The almost invariably fatal character of the accident, after suppurative pleurisy had ensued, produced a great impression on my mind, and I immediately set about devising some plan that should meet the indications. I was greatly encouraged in my endeavors by the following case:

CASE II.[2]—A man entered the ward one day who had been shot through the left arm by a pistol-bullet that also pierced the chest-wall, chipping off a fragment of the sixth rib, and carrying into the chest-wound a piece of the patient's flannel shirt. Being called to the patient almost immediately after his admission, and perceiving no sign of hemorrhage, I at once removed with my forceps the small fragments of bone and cloth that lay in the wound, and sealed the wound hermetically. Pleurisy with effusion ensued but the patient recoveued.

The other cases I briefly note as follows:

CASE III.—H. C——, aged twenty-nine, was stabbed in a brawl on December 25, 1868. The knife entered the lung, as was supposed, through the fourth left intercostal space. The wound was hermetically sealed, and the patient was discharged cured in sixteen days.

CASE IV.—W. L——, aged thirty, received a pistol-shot wound in the left side on July 4, 1867. Bloody expectoration followed. The wound was tightly closed, but on the sixteenth day pleurisy with effusion had developed. Under blistering the fluid disappeared.

CASE V.—J. S——, aged forty-one, received a pistol-shot wound of the thorax on November 16, 1867. The bullet entered the right side of the chest, between the third and fourth ribs. He died on the fourteenth day of empyema. Six pints of fetid matter were removed by me at the post-mortem examination from the right pleural cavity. There was one pint of bloody serum on the left side.

CASE VI.—C. N——, aged twenty-nine, received a pistol-shot wound of the chest, March 27, 1868. The bullet entered the second right intercostal space. The wound was hermetically sealed, but the patient died in about two weeks of empyema. As in the former instance, at post-mortem examination the right lung was found collapsed, while in this instance about a quart of greenish pus occupied the right pleural cavity.

I subsequently found, as is now well understood, that the hermetically sealing of a wound does not necessarily prevent suppuration. Consequently it became a matter of the first importance to have a method of successfully treating the empyema which may follow any line of treatment. For I will venture to add, at this point, that suppuration cannot always be prevented, even under the most rigid antiseptic principles.

My first attempt in this new direction was during the year 1868, in the case of a policeman (CASE VII.) who received a shot in the left lung, the exterior wound being situated in the anterior wall of the chest, a little to the left of the heart. After suppurative pleurisy had developed in the regular fashion, I attempted to pump out the matter daily through the single opening, and the instrument here delineated (Fig. 1) was made for me at the time by my friend Dr. Allan McLane Hamilton, then a student of medicine.

Dr. Hamilton's instrument was, as is seen by the cut, extremely simple in its mechanism, and answered the purpose for which it was made. The metal plate *A* was fitted with a short cannula, *E*, placed over the wound, the cannula entering and remaining in the pleural cavity. The plate was then fastened down to the surface of the chest by adhesive plaster. The stop-cock *F*, having been closed so that air could not enter by the evacuating tube *C*, the trocar *B H* was gently passed through the cannula *E*, so as merely to clear the wound. [It was intended, in other cases where the chest was to be punctured, that this trocar and cannula be introduced simultaneously into the pleural cavity.] It was then quickly removed and the cap *D* was screwed into the upper opening of the plate, effectually preventing the ingress of air through the cannula at this point. Then, by applying an ordinary Davidson apparatus to the tube *C*, the matter could be pumped out.

The advantages and disadvantages of this instrument were, in the main, those that are associated with the ordinary aspirators in use to-day; though this particular evacuator had some advantages over them, in so far as that the pleural cavity was at all times accessible, while the pus could be withdrawn as frequently as thought desirable without making a fresh puncture of the chest. It is also interesting, from an historical point of view, that the instrument antedated the aspirator of Dieulafoy; for it will be remembered that he first brought "aspiration" to the notice of professional men in November of 1869, when he read a paper on the subject at a meeting of the French Academy.

---

[1] Read in part before the Clinical Society of the New York Post-graduate Medical School and Hospital, March 3, 1888.

[2] The patient was a printer, aged thirty-three, who entered the hospital on May 23, 1868.

Personally, while I have recognized aspiration as desirable in some cases of pleurisy with effusion, and have practised it successfully, I have never believed that aspiration is a sufficiently radical measure in pyo-thorax; and it proved unsatisfactory in my case here mentioned, largely from an error in my method, not from any fault of the instrument, which accomplished the work intended for it to do in a satisfactory manner. Of course I am willing to admit that aspiration in suppurative pleurisy is capable of effecting some cures, as Dr. Bowditch[1] showed years ago.

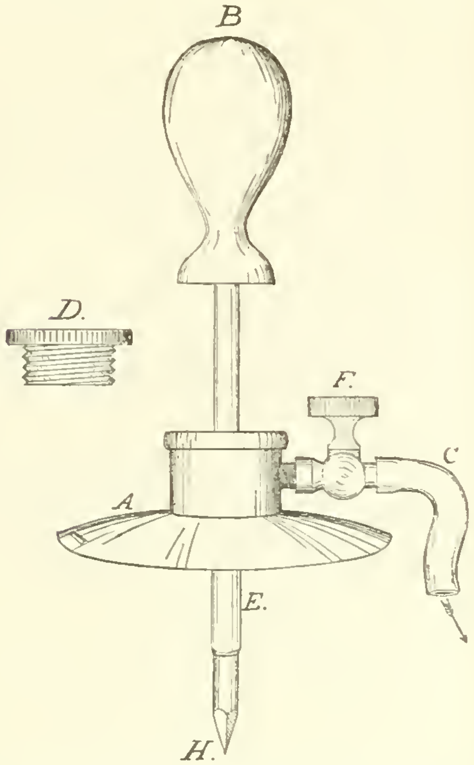

FIG. 1.—Hamilton's Evacuator, from a Drawing by the Inventor. *A*, Plate to be bound to chest; *B*, *H*, trochar; *C*, evacuating-tube attached to syringe or for drainage; *D*, cap; *E*, cannula; *F*, stop-cock.

At this point it is convenient to note that Dr. Bowditch (*American Journal of the Medical Sciences*, October, 1850) had previously used and recommended to the profession an apparatus made by my friend Dr. Morrell Wyman, of Cambridge, Mass., and quite similar in its mode of action to the Weiss stomach-pump. His apparatus consisted of a trocar a little larger than the ordinary exploring trocar, and a silver cannula, with a stop-cock in silver, as light and small as possible, capable of being connected with a syringe by an intermediate piece of brass, also provided with a stop-cock. The trocar and cannula were plunged into the fluid, and having withdrawn the trocar, leaving the cannula, the double-barrel syringe was applied, the effusion slowly drawn away, until the lung had undergone as much expansion as it could with safety. But consider for a moment the mortality According to Aitken,[2] in 24 of Dr. Bowditch's cases, where "pus flowed at the first tapping," only 7 recovered; 7 died—a mortality of fifty per cent.[3]

Nor have I been hopeful of the more radical method of simple incision, for, according to Dr. Fraentzel,[1] who advocates it, and gives most particular and methodical rules for the operation and the after-treatment, the mortality was forty-five per cent. And yet his method was based on careful antiseptic measures.

Some two or three years later, while in the German and French military hospitals, I saw quite a number of cases like those already described, where empyema had followed upon gunshot wounds of the chest; sometimes, indeed, where the patients had recovered in part from the acuteness of the attack, but were gradually losing health and strength from month to month, owing to the exhaustion incident on long-continued purulent discharges. Keeping in mind my experience in the past, I resolved, when the opportunity offered, to try a more radical method. It came in the year 1877.

Case VIII.[2]—A boy was brought to me in January of that year. He was about two years of age, and had been under medical care some three weeks, having been sick in all about four weeks with what the parents called "erysipelas." The right side of the chest was swollen anteriorly. It was also red and painful. The incision that had been made was in the second interspace (if I remember correctly), and the mother thought that about half a pint of matter had escaped at the time of the operation. When I saw the child it was feverish, and in a septic condition. I introduced a long bullet-probe into the opening and passed it about freely in various directions. When the child was made to sit up, the matter discharged freely. I then washed out the cavity with a two per cent. watery solution of carbolic acid by introducing a flexible catheter and syringing through it. The child bore the procedure well, and after it slept nursed, and took beef-tea and milk-punch. On the day following I again introduced my probe, and finding that matter had collected in about the same quantity as the day before, and that carbolic acid did no harm, but rather benefited the child, I resolved to try to secure a perfectly free exit for the pus, which I did in the following manner: Passing my probe along the inner surface of the ribs I pressed it against the fifth intercostal space, and then, cutting down upon the end of the instrument, brought it out through the opening. In these cases it is well known that the orifices have a strong tendency to close; to avoid such a mishap I attached a number of stout ligatures to the end of the probe, and, drawing the instrument through, carried the ligatures with it. For safety's sake I took the extremities of the ligatures, as they depended from the two incisions, and tied them together. In this way, of course, the discharges passed through two openings, and the mother was directed to give the setons "a little pull" whenever the matter did not escape easily enough. The child now was materially better, took its nourishment freely, and played with its toys. The temperature was 102° F. The wound was syringed out daily with the two per cent. solution of carbolic acid. After this treatment had been begun the temperature fell a little at first, but in a few days suddenly returned, while the discharge diminished; the child refused everything except the breast, and I thought the end was near. On the third day of this complication I found an area of dulness above the point of incision, with finely crepitant râles. There was also a troublesome cough. Pneumonia had ensued, while, to add to our troubles, the child took the measles about a week later. Its eyes were suffused and the body covered with a measly eruption. The temperature rose to 104¼° F., and, with all the opportunity offered for the free escape of matter, the phlegmonous inflammation had not entirely disappeared. More than this, there was a decided fulness just above the free border of the ribs and below the first incision. I hesitated some time before incising at this point, because I was

[2] Science and Practice of Medicine, vol. ii., p. 587.

[3] Of the remaining 10 it is presumed no record was kept. But this bad record is even surpassed by an analysis of all his 75 cases, wherein it appears that only 29, about thirty-eight per cent., recovered entirely (loc. cit.).

---

[1] Ziemssen: Cyclopædia of Practice of Medicine, vol. iv., p. 722.

[2] This case was reported in part under the head of Demilt Dispensary Reports, New York Medical Journal, July, 1877.

afraid of cutting into the peritoneal cavity. Finally, on March 1st, I made the incision and was relieved by seeing the pus squirt out. No counter-opening was made. A tent of lint was then introduced. In a few days oakum was substituted for the lint. But there was not as yet entire relief. A fulness with pain and a doughy swelling subsequently appeared in the right iliac region. I could not account for this new development but on the supposition that pus had passed downward through pouching of the diaphragmatic pleura. I made an incision about one inch above the anterior superior spine, and was greatly relieved by finding a collection of matter.[1] This was the last incision. By May 7th all the openings had closed, and so, after a long and obstinate struggle with the disease for about five months, it finally yielded.

I now exhibit the boy to you. It is more than eleven years since the operation, and you have a good opportunity of seeing the final result. There is hardly any appreciable difference between the measurements of the right and left sides, and the boy is perfectly straight. Both sides of the chest dilate about equally and he is said to be in perfect health, though one may detect that the respiration is a trifle harsh. This may be due to a slight cold.

This case illustrates a well-known fact that in empyema. no matter how free the drainage is made at one particular spot, areas will remain where matter will be chambered up. Dupuytren[2] saw a case in which sixty-three separate fistulous openings formed during the attack.

The operation which I did on this occasion was a modification of Chassaignac's described by him in his work which was published in 1859, for he appears to have been the first to have advocated a *counter-opening*. His plan, however, was different. He employed a trocar with a curved needle about a foot and a half long.[3] Introducing it at the point where suppuration was indicated, he carried it through the purulent collection, piercing another intercostal space. These openings having been enlarged, he threaded his trocar needle, and, attaching the silk thread to a drainage-tube, withdrew the needle and drew the drainage tube after it. Chassaignac reported two cases cured out of three. Campbell de Morgan, of London,[4] operated successfully in a few cases, following the example of Chassaignac. The operation was also advocated by Gosselin, of Paris, and some have written favorably of it, though I have not been able to find any record of their cases; others have condemned it in unsparing terms. Fraentzel, for example, in an article (Ziemssen's "Cyclopædia," vol. i., p. 725) says: "No physician would now carry out drainage of the pleural cavity as first advocated by Chassaignac."

Since neither Flint (in his last edition), Quain, nor Fagge mention the subject of through drainage, it may fairly be inferred that the operation has not been generally practised in suppurative pleurisy.

It is singular that this operation of Chassaignac is also rejected by so excellent a surgeon as Mr. Bryant;[5] yet he advocates free incision and subsequent daily washing of the cavity, and records two good results. And though the counter-opening is recommended by the late Dr. Gross,[6] he rejects the drainage-tube as "harsh and dangerous."

J. Clifford Albutt has about the same ideas of the drainage-tube, though he recommends the counter-opening, saying that it should be practised after one or two days, according to the state of the patient. The opening should be made sufficiently large to admit the passage of a sound, which can be passed about in the pleural cavity so as to determine the lowest point in the axillary or infrascapular line, and an opening should be made upon the point of the instrument so as to drain the cavity of the last drop. After the pus has run out the upper opening is to be closed. No drainage-tube is used, and no injections are permitted.[1] He does not give us the percentage of success. At the present moment, however, a manifest change of opinion is taking place toward a more radical measure than simple incision. Thus Dr. J. Q. Blake[2] reports 16 cases out of 19 saved (84.2 per cent.), though of these cases only 10 were reported well at date of writing. Dr. A. T. Cabot saved 11 out of 14, or 78.5 per cent.[3]

The following clause, in my opinion, taken from an excellent source, is worth careful consideration as reflecting the attitude of many of our best practitioners at this present time.

"In the hands of Boyer, Delpech, Dupuytren, and Sir Astley Cooper the bistoury gave bad results, but as now used, with all modern appliances and antiseptic precautions, it affords infinite relief and many cures. We claim that by early pleurotomy, with Listerism scrupulously used at every stage of the operation, and, if necessary, with detergent washings, the mortality from this extremely grave disease can be very materially lessened."[4]

CASE IX.—The following case I saw in Dr. Billington's practice. It was reported a little less than ten years ago.[5] J. C——, aged six, was first seen by Dr. Billington and Dr. A. A. Smith on July 16, 1878, and pus was withdrawn from the pleural cavity by an aspirator. On the 17th, at the invitation of Dr. Billington, the child was seen by Drs. W. T. White, A. A. Smith, O. B. Douglas, M. J. Roberts, and myself. An incision was made in the fifth left space, half an inch to the left of the nipple. Twelve ounces of pus were withdrawn. It was proposed by some to make a counter-opening, and introduce a drainage-tube, but there was opposition by others to this procedure on the ground that a drainage-tube would probably prove a source of irritation to the pleura when the lung began to expand. Accordingly, further operation was deferred. On the next day I saw the case with Dr. Billington, but the opening had closed. It was, however, reopened and the cavity washed out with two per cent. tepid carbolic acid water. A tent was then left in the wound. On the 27th I was again invited to see the patient with Dr. W. T. White, with a view to a counter-opening, as the matter did not discharge with sufficient freedom. But now, owing to the crowding of the ribs from the sinking in of the chest, the probe could not find any intercostal space, and the conclusion was reached that a counter-opening should have been made at an earlier date. To add to the difficulties, it soon became plain that we had to do with a pneumo-thorax, as after the washing the child would bring up by the mouth the fluid injected through the wound. A similar case is recorded by Trousseau[6] in a child aged six, where recovery ultimately ensued.

It subsequently appeared, from the introduction of a catheter, that there were two cavities, one an intrapleural, the other a pulmonary. If, however, the external wound closed, as it did on one occasion when there was no escape of the pent-up secretions for two days, the symptoms became very alarming, and once the child appeared to be moribund from the toxic influence of the septic matter. Immediate relief followed the reopening and thorough cleansing of the wound. The patient subsequently recovered though no counter-opening was made; but phthisis developed some years later. This case is remarkable, from several points of view. It illustrates (1) the toxic effects on the system of pent-up secretions; (2) that if a counter-opening is to be made it should be done at an early stage of the disease, else the operation by the double incision may be impossible; and (3) that pulmonary cavities may be advantageously treated by direct injection. Certainly the objections laid against this operation in that it allows air to enter the pleural cavity had no weight on this occasion, because air had existed in the pleural cavity before the operation.

---

[1] A somewhat similar case was observed by Chappe, who finally made an incision in the hypogastric region to reach pus that had migrated from the pleural cavity. The case terminated successfully. Chassaignac: Traité pratique de la Suppuration, vol. ii., p. 341. Fagge also reports a case resembling mine in many particulars, Practice of Medicine, vol. i., p. 948.

CASE X.—C. L. W——, Belleville, N. J., a gentleman, aged twenty-seven, consulted me in the year 1884, stating that in 1883 he had been taken with "pneumonia." Being sent by the physician whom he consulted in New York to the Adirondacks, he came under the observation of Dr. Riley, of Au Sable Forks, who discovered that he had pyo-thorax. Accordingly, on the next day he punctured the chest, drawing off four quarts of matter, and on the following day two additional quarts. In the spring of 1885 he consulted me in reference to the continued discharge from the opening. I recommended through-drainage, and requested his physician, Dr. Riley, to use my instrument for that purpose. The operation was performed successfully by Dr. Riley, and his health improved steadily from that time. He, however, appears to have been taken in the summer of the same year with something like apoplexy, which carried him off in a few moments. The sinus was practically healed at the time of his death.

This is an instance of an adult who had been suffering for two years from the continuous discharge of an empyema. An operation carried out in the way described in Case VIII. restored him to apparently good health. Such an example is surely a good test for the efficacy of the method.

But supposing for a moment that the fistulous opening had been treated by the expectant plan, let us hear what Fagge says: "A pleural fistula may go on discharging for five, ten, or fifteen years, or even longer, until lardaceous changes develop themselves in the abdominal viscera and cause death by renal dropsy." "At the same time, all the structures which surround the pleura become dragged inward so as to reduce it within the smallest possible limits. The ribs fall in and may almost come into contact with one another; they remain motionless during inspiration, or (as was once observed by Dr. Gee) their anterior parts may actually recede and move backward each time that the healthy half of the chest expands and draws the sternum forward. The dorsal spine becomes curved so as to present a concavity toward the affected side. The shoulder sinks, the diaphragm is dragged upward with the abdominal viscera beneath it, etc."[1]

CASE XII.—The case which I now show you I saw with Dr. Seneca D. Powell about ten days ago. There was the usual phlegmonous inflammation of the wall of the chest, with the other characteristic symptoms of pyothorax. I recommended through drainage, and it was performed by Dr. Powell on Monday week, 1888. The child had no unfavorable reaction after the operation, though about three pints of matter were removed. The probe was passed in through an incision in the ninth intercostal space anteriorly, passing beneath the pericardium and out posteriorly just beneath the angle of the scapula. Five ligatures of twisted silk were then carried through, being attached to the end of the probe. Their ends were then fastened together.

The history of this patient is thus given by Dr. Burwell, resident physician to the Post-graduate Hospital, where the child was taken after it had been decided to operate. "N. B——, two and a half years of age, was taken sick at home about the third week of December, 1887. The symptoms, as described by the mother, were those of convulsions, with a bad cough and labored breathing. The child was thought to have simple pneumonia, but entire recovery did not take place, and, in fact, the mother noticed that the left lung did not expand. About March 1st a lump appeared in the left side anteriorly, just above the tenth rib. Just prior to March 7th there was pointing, with considerable phlegmonous infiltration of adjacent parts. On March 8th an incision was made by Dr. Powell at the seat of the pointing and an aluminium probe carried through the pleural cavity; a counter-incision was made, to admit of the instrument being carried completely through, from one side to the other. Setons of heavy silk were carried through and their extremities tied together. Temperature prior to the operation, 97.8° F.; pulse, 114; respirations, 30. No improvement followed the operation; in fact, there was no change apparent in the child. On March 17th the temperature rose to 102° F., the pulse to 122, the respiration to 40. Strict antiseptic precautions had been carried out. Under free stimulation, however, these unfavorable symptoms disappeared, and the temperature, pulse, and respiration became normal. On April 4th, however, there was a recurrence of the fever, the temperature reaching 103° F., the pulse 142, the respiration 60. Twenty-four hours later the child was dead. The drainage was at all times perfect, though as a measure of precaution the abscess-cavity was washed out almost daily with a weak antiseptic solution."

This little patient was an unfavorable subject for an operation; coming of a phthisical family, reduced almost to a skeleton, deprived of mother's milk, with pyopneumo-thorax from the time she was first seen, it was an instance where a cure could hardly have been anticipated.

CASE XIII. is described by Dr. Richard N. W. Horner, of this city, with whom I saw the patient in consultation on March 20, 1888.

"Frank F——, aged seven, was seen by me on Saturday, March 17, 1888. He had been ill for eight weeks. Had been healthy previously. Had lost considerable flesh. Was pale and thin when I saw him. He complained of pain in his chest on the left side, had cough and thick, tenacious expectoration; was sleepless. No marked fever (99.2° F.); dulness all over the left side of the chest. Anteriorly it amounted to flatness, extending from the seventh or eighth rib upward till it was lost in the cardiac dulness. A tumor was seen at the lower border of this flatness about an inch to the left of the nipple. The diagnosis of empyema was made, this tumor evidently being the point at which pus was trying to escape.

"On the following Tuesday Dr. Satterthwaite, assisted by Dr. Crowell, opened the chest at the point of the abscess anteriorly and at a corresponding point posteriorly, chloroform being used as the anæsthetic. Pus poured out freely as soon as the openings were made. The exact amount was not determined. A few strands of braided silk were drawn through, and the wounds dressed antiseptically. After the operation the expectoration entirely ceased for forty-eight hours. After the chest was washed out it stopped again. The solution used for washing was bisulphate of quinine. His treatment has been stimulating and tonic. He is gaining flesh and strength, and is comparatively comfortable."[1]

At this point I may say that the operation I have described is a comparatively simple one, and, from the point of view of my experience, is safe. In this connection I may mention a case that bears out this statement.

CASE XIV.—On the evening of April 12, 1888, I saw, at the request of my friends Drs. E. C. Titus and W. A. Shufelt, a patient who had been slowly convalescing from an attack of right-sided pneumonia. The patient was a man of middle life, of strong physique, rather inclined to be fleshy. Everything had progressed satisfactorily with the right lung, but shortly before our visit an effusion had been formed at the left base, while almost simultaneously there appeared in front immediately below the free border of the ribs and to the left of the median line a boggy swelling that showed some inclination to point. The patient, however, was suddenly taken with a violent attack of expectoration, and brought up about a pint of matter. Finding, however, that there still remained the physical signs of a liquid which I presumed to be purulent, I aspirated along the line of the pointing, carrying my aspirator needle upward and backward. I entered a large cavity, but could obtain no matter, though the largest needle of the Potain instrument was used. Failing from in front, I turned the patient around and aspirated him from behind in two places, each time with the large needle. About four ounces of bloody serum was the only result. The patient was in bed, extremely weak, and in a septic condition. He began improving, however, after the operation, and now is convalescent, though Dr. Titus informs me that he has the well-defined signs of a large pulmonary cavity.

---

[1] Fagge, vol. i., p. 940.

[1] I understand that the little patient has now (November 9, 1888) made a good recovery.

In this instance I presume that pyo-thorax existed, constituting a circumscribed abscess, which was aiming to discharge externally when the pulmonary pleura gave way, and, the matter being forced into the air-tubes, was expectorated in the manner that has been described. At another point in the pleural cavity was a circumscribed collection of non-purulent fluid, which I removed by aspiration.

The instrument which is applicable for establishing the point for a counter-opening in pyo-thorax is a probe about thirteen inches in length (Fig. 2). It is about the length of a Hamilton's bullet-probe, but is made in one piece, either of copper or of aluminium, and should be quite stout. It is well for it to have a cleft at one extremity, in order to carry the seton. In the accompanying cut one sees in the illustration marked 1 the probe in miniature; in 2 there is a sectional view of it, still somewhat reduced from the normal size. I have been in the habit of carrying through the pleural cavity several stout ligatures, the object being to facilitate the escape of pus on the one hand, and to obviate the use of a drainage-tube, which is difficult to pass between the ribs from the back; whereas, if a puncture can be made from behind, a seton can in all cases be introduced. In addition, it may be said that ligatures will cause less irritation to lung-tissue against which pressure will be made as the lung expands.

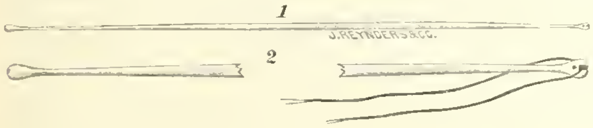

Fig. 2.

From a consideration of the foregoing cases it will be seen that the operation of "through drainage" is one that can be practised both in infancy and in adult life, though sometimes, where the sinus has been discharging for a considerable time (Case IX.), it may be difficult or impossible to make the entry into the pleura from behind, owing to the insufficient space between the ribs; and yet, even when the sinus has been discharging more than two years, the entry has been successfully made (Case X.), and I think it well to emphasize the matter on this occasion when I am entering a plea for the radical treatment of pyo-thorax. I will concede that there may be extreme cases where the incision or excision of ribs may be necessary.[1]

But in all such instances I think the surgeon will do well to consider whether the object to be attained cannot be accomplished by a less radical method. I have never, in my experience, seen cases that would call for the cutting away of a considerable portion of the bony walls of the thorax, as recommended by Estlander, and I can only conceive that the operation is admissible when the unfortunate patient has failed to have the benefit of intelligent medical attention during the earlier stages of his attack. It is singular that writers should have differed so greatly as to the point of election in puncturing the chest. Hippocrates and Vesalius elected the ninth left and eighth right; Paul Æginata, the fifth space; Scultetus, the sixth; Paré, the fourth; Chopart, the tenth.

To summarize: 1. The operation of "through drainage," the merit of which belongs essentially to Chassaignac, is one that can be successfully practised both on infants and on adults, though cases may possibly occur in chronic empyema where it is not practicable.

2. It is the operation that should be attempted in pyo-pneumo-thorax at the earliest possible moment; and in all cases of chronic empyema. In acute empyema the indications are not so plain.

3. The location of the openings is not so important as that one, at least, shall be in the most dependent part of the thorax, according to the position that the patient occupies. If in bed, one opening should be in the axillary line; if not confined to bed, preferably behind and about four inches below the angle of the scapula and four inches from the spines of the vertebræ.

4. The cavity should be washed at least twice daily with some antiseptic solution, and all known means should be adopted to permit the free escape of matter.

5. In acute empyema, where as yet there is no external opening, aspiration should be resorted to for three reasons: (*a*) To determine the character of the liquid in the pleura, and (*b*) to draw off a portion of the liquid before resorting to *through drainage*—by this latter procedure the lung is allowed an opportunity to expand and a possible pulmonary hemorrhage or œdema is prevented; (*c*) because under one or more aspirations recovery has ensued.

6. When, however, the incisions have been made they should be enlarged so that they cannot close, and any subsequent contraction of the orifice should be prevented by using some form of dilator.

7. Should a new collection of matter be found in the pleura, it may be treated in the same manner as the first collection.

8. The success of treatment depends chiefly upon providing a free exit for the matter as soon as it forms, but nutritious, and even stimulating, diet should be enforced.

9. It is a comparatively easy and safe operation, the only danger being puncture of the heart, liver, or spleen.[1]

10. To judge by my cases in which the operation of through drainage was performed (Nos. VIII., X., XII., XIII.) the percentages of cures may, I think, be fairly placed at seventy-five per cent. That it may be of great benefit in phthisical cases where pyo-thorax or pyo-pneumo-thorax has developed I have no doubt in my mind.

11. The radical operation of exsecting a rib, first performed by Celsus,[2] then by Peitavy and Roser, and later popularized by Estlander,[3] is an operation that may occasionally be necessary in neglected cases.

17 East Forty-fourth Street.

The Sanitary Condition of Nice is said to have been notably improved within the past year by a new system of sewerage and of disposal of night-soil. Since the completion of these works the mortality of the city has decreased from 32.77 to 24.34 per thousand inhabitants.

---

[1] An operation revived by Roser, Arch. für Phys., vol. vi., I., but first practised in this country by Warren Stone, of New Orleans, Medical Record, June 9, 1883.

[1] Though it seems hardly worth while to state that the operator should see to it that he does not puncture such organs as the heart, liver, or spleen, they have all been punctured at various times, and with fatal results in some instances.

[2] Celsus says: "'Tis common for fistulas to extend beneath the ribs. When this case occurs the rib in that part must be cut through on both sides and taken out, lest anything corrupt be left within." Celsus, trans. by James Grieve, M.D., London, 1756.

[3] Estlander recognizes the value of the counter-opening, but states that when the operation does not succeed resection of a rib may be called for. His results were, in 7 cases, 2 cured, 4 relieved, 1 died. He makes a single incision and removes portions of two or more ribs. He then inserts a large drainage-tube. (Estlander, Resection des Côtes dans l'Empyême chronique, Revue mensuelle de Méd. et de Chir., iii., 1879.)

THE PHONOGRAPH IN PHYSICAL DIAGNOSIS, WITH EXPERIMENTS, AND ITS FUTURE.

By J. MOUNT BLEYER, M.D.,

NEW YORK CITY.

Although some ten years have elapsed since Mr. Thomas A. Edison startled the world by inventing a machine that stored up sound and reproduced it at will, it is only within the past few months that this wonderful invention has been brought to such degree of perfection as makes it of practical utility to the public at large. Some time has passed since I began to investigate the practicability of this machine, so as to give to the medical world a better and more certain means of teaching, recording, reproducing, and demonstrating the physical signs or sounds of the normal as well as of the diseased condition of the heart and lungs.

At this early stage of my experiments I must say that I predict a great future for it, and the opening of a new field for investigation in physical diagnosis and teaching.

I am not ready to give an entire account of my experiments with the phonograph in this line of investigation, but will only touch upon some of the already known and practical points which I have been able to satisfy myself of thus far.

Before going into the details of some of the points of my late experiments, I think it is necessary that I give a description of what the phonograph is, does, and how the sounds are recorded and reproduced, so that those who are not familiar with this apparatus may grasp the ideas connected therewith.

The original phonograph, while valuable as demonstrating the possibilities of human invention, and as opening up a field of research in acoustics previously unexplored, lacked the elements essential for practical use. The metallic, and sometimes indistinct, sound-waves that were emitted from the primitive tin-foil, the lack of proper mechanical appliances, the want of a suitable material for the impression-plate, and numerous other defects, made the invention useful principally in the laboratory of the scientist or in the museum of curiosities.

These early defects have at last been all overcome, and the perfected phonograph (so called by Mr. Edison), for the multitudinous purposes for which it can be used, is as practical as the type-writer or the telephone in their respective spheres.

Since the time of Lucretius the movements of atoms have been invested with an intense interest for philosophers and scientific students, and the wave-motions of light, heat, and sound have engaged, with a constantly increasing degree of importance, the attention of modern investigators. When we consider the relations of these motions to mathematics and to music, the conception of Pythagoras, that number and harmony constituted the principle of the universe, does not seem to be very far out of the way. In the phonograph Mr. Edison finds an illustration of the truth that human speech is governed by the laws of number, harmony, and rhythm, and by means of those laws we are now able to register all sorts of sound and all articulate utterances, even to the lightest shades and variations of the voice, in lines or dots which are an absolute equivalent for emission of sound by the lips; so that, through this contrivance, we can cause these lines and dots to give forth again the sounds of the voice, of music, and all other sounds recorded by them, whether audible or inaudible.

For it is a very extraordinary fact that, while the deepest tone that our ears are capable of recognizing is one containing sixteen vibrations a second, the phonograph will record ten vibrations or less, and can then raise the pitch until we hear a reproduction from them. Similarly, vibrations above the highest rate audible to the ear can be recorded on the phonograph, and then reproduced by lowering the pitch until we actually hear the record of those inaudible pulsations. Mr. Edison gives the following for an example, in order to make the general idea of the recording of sound more clear:

"We have all been struck by the precision with which even the faintest sea-waves impress upon the surface of a beach the fine sinuous line which is formed by the rippling edge of their advance; almost as familiar is the fact that grains of sand sprinkled on a smooth surface of glass or wood, on or near a piano, shift themselves into various lines and curves according to the vibrations of the melody played on the piano keys. These things indicate how easily the particles of solid matter may receive an imparted motion, or take an impression from delicate liquid waves, air-waves, or waves of sound. Yet. well known though these phenomena are, they apparently never suggested, until within a few years, that the sound-waves set going by the human voice might be so directed as to trace an impression upon some solid substance, with a nicety equal to that of the tide in recording its flow upon a sand beach."

Description of the Phonograph. How the Sounds are Registered and Reproduced. — The cylinder is run by an electric motor of a special kind, differing from all others which are now used, in place of the old clock-work. This motor turns the cylinder noiselessly, uniformly, and easily. Instead of tin-foil, Mr. Edison now makes use of a cylinder of wax for receiving the record of sound-pulsations, as in the original experiment. One diaphragm ("the recorder") receives these pulsations, which are incised on the wax, in exceedingly fine lines, hardly visible to the naked eye, by means of a small point pressing against the wax. A turning diaphragm pares off the surface of the wax, removing any record which may previously have been left there, and smoothing the way for whatever you wish to speak or transmit into the "recorder." When you have finished speaking, or recording, etc., two simple motions bring the reproducing diaphragm into place, directly over the wax, and this diaphragm, provided with a very delicate but durable needle, takes up and reproduces the vibrations registered in the fine lines of indentations, bringing them to the ear by means of a tube. Sometimes, indeed, one can hear the recorded words as they are thrown off by the needle from the revolving cylinder, without using a tube at all, and simply by putting the ear close to the wax. The adjustment of these receiving and transmitting diaphragms, known as the "recorder" and the "reproducer," are very exact, but very easily arranged, and a machine, once adjusted after being set up, will run well, with very little attention or readjustment, for a long period of time. The battery will last for six weeks or more if placed out of the way. A scale and indicator, running the whole length of the cylinder in front, enable you to observe at what point you began talking or recording, etc., so that the reproducer may be set at that point on the wax as soon as you wish to take off the record which you impressed or stored up. Another very handy attachment supplies a key for suspending the reproduction of sounds when it is going too rapidly for the listener or copyist. A second key, when pressed down, will run the reproducer back, so as to repeat anything which has not been clearly understood, and this may be done any desired number of times. A single wax cylinder, or blank, may be made use of for fifteen or twenty successive records before it is worn out. But if the record is to be kept, the wax blank must not be talked upon or have anything transmitted upon it again, and is simply slipped off from the metal cylinder and filed away for future reference.

For instance, if you have made a physical examination of the lungs or heart by means of the phonograph, and you would like to have and keep a record of this case. If, then, in the course of a week or month, or even a longer period has elapsed, and you then for some purpose, such as teaching, or consultation, or for demonstration to a class of students, or otherwise, would again like to reproduce all of the physical sounds of that particular case, all that is necessary to bring to your ear all the sounds of that case and period of time before you, simply fit on that wax cylinder which has that record to the phonograph, and listen to it. At once it talks and gives forth all that has been registered upon that wax cylinder, and again your patient of that period of time is before you, as a living example and model, for whatever purpose you wish to make use of him. One of these wax blanks will repeat its contents thousands of times with undiminished clearness.

I have long waited for the perfection of Mr. Edison's phonograph, in order that I might again satisfy myself and resume experimenting with this instrument in this branch of medical science; all of the old obstacles have been overcome, and it has been put before us as the perfect phonograph.

By the kind permission of the Metropolitan Phonograph Company, I was able to gain access and carry out my further experiments. There was long a wish to place into the hands of our profession an instrument by which we could record, reproduce, and demonstrate sounds, so as to teach our students the physical sounds from the stage of the college, or directly from the phonograph. The sounds can by this means be previously stored up, in these wax cylinders, direct from patients that are at our disposal in the hospitals, or from our private cases. Thus, also, all physical sounds can be stored up and preserved for any length of time, so that one could have a collection of cases to illustrate from the old, as well as from the new, cases, some interesting and profitable points of physical signs at will. This is done by simply replacing upon the steel coil the recorded wax cylinder.

From what observations I have already practically made, I am satisfied that the phonograph has a great future, and has opened up an entire new field of investigation in that line.

Experiments.—The method which I adopted in making these experimental physical examinations by the phonograph was carried out in the following manner:

The phonograph was placed on a suitable table before me; a tube in the shape of the deaf conversation-tube was then attached to the recording cylinder of the phonograph; the other end was placed on that part of the chest which was to be explored; then the phonograph was set in motion before placing the tube in contact with the chest. In order to register or record upon the wax cylinder that part of the chest which was intended to be examined, it was found necessary, either before or directly after examining any part, to register by its anatomical name that part of the chest. This was done by speaking into the phonograph, so as to be able, in reproducing, to distinguish those physical sounds found in one part from the other.

For example, if I intend to examine the supraclavicular region, I speak into the phonograph while in motion, before placing the tube on the chest, "*Supraclavicular region.*" By so doing, these words were directly registered. I now place the tube on that part of the chest and examine slowly and thoroughly. In this way I continued to explore the entire heart and lungs. It will be found advantageous to allow the cylinder to make a number of revolutions before removing the tube to another part, in order that more than one respiratory heart-sound might be registered.

This is also to be carried out on examining the heart-sounds.

When I was finished with my examination, I returned back the reproducer, so as to repeat that which was registered during the examination. The phonograph was now set in motion; a direct attached stethoscope was applied to my ears, from the phonograph. All the sounds were heard, in their varied pitch and tone as they came along, with perfect clearness. The words and sentences that I had spoken into it, for the purpose of recording the landmarks, were all reproduced.

These experiences have taught me in how many other ways and manners the phonograph may be practically applied to aid us for all purposes.

With some extra experimenting I was able to apply the use of the phonograph in such a manner as to throw the physical sounds, which had been previously registered upon one of these wax cylinders, into the auditorium, and thereby teach directly a larger class of students. It is a known fact that one can learn the tune of a song quicker, when he repeatedly hears it, than when he tries to remember such tones and sounds as they are taught by means of words without the material and thought together simultaneously.

To carry out my purpose for this manner of teaching and throwing out the sounds some distance, I was obliged to make the following additional trials, which finally led to success.

To adapt the phonograph for the above aim, the sounds had to be magnified by means of the microphonic stethoscope, thence transmitted to the phonograph, and upon the cylinder a trumpet of tin was then made use of, which acted as a resonator for the purpose of throwing out the sounds in a still more magnified state. The trial proved to me that, with some extra attachments, it will be the instrument for carrying out that purpose.

It is further possible to construct a physical-sign cabinet which has all registered cylinders representing the different diseases of the lungs and heart. When one wishes to study any of the normal or abnormal sounds of the heart or lungs, he can pick out of his cabinet that cylinder which has registered upon it such physical sounds.

From the phonograph, as it is now constructed, a half-dozen or more can study any physical sound by means of, a branch stethoscope attachment which I have constructed.

I hope in a few weeks to have finished my entire investigation on this subject, and will then be able to demonstrate before some of our medical societies its future possibilities.

It must be borne in mind that I am not talking now of things which may be made possible, but the functions above mentioned are those which the present perfected phonograph is able to fulfil at this moment. To use the phonograph a little instruction and practice are needed, but much less than the type-writer requires, and hardly more than the training needed for the operation of a sewing-machine.

Various other uses for which the phonograph is now fully ripe might be mentioned, but I am not ready to give memoranda of these.

83 Second Avenue.

Spinal Manifestations of Gonorrhœa.—Drs. Hayem and Parmentier describe certain affections of the spinal cord as directly due to gonorrhœa. The authors have endeavored to extend the range of certain observations made by recent writers in this country and in England, and add to their precision. It seems that in a few persons suffering with gonorrhœa such spinal phenomena are met with as a zone of pain, fulgurant pains in the lower limbs, double sciatica, hyperæsthesia, exaggeration of the patellar reflex, epileptoid trepidation, enfeebled motility, and atrophy of the muscles of the legs and thighs. Ordinarily these phenomena appear in company with articular affections, and with them show periods of exacerbation and amelioration.. The time of their onset seems to bear no definite relation to that of the beginning of the gonorrhœa. They may be grouped in three classes: Disorders of sensibility, those of motility, and those of both sensibility and motility. The manifestations are always confined to the lower limbs, and the spinal lesion is generally a congestion or a meningo-myelitis affecting the posterior or the postero-lateral columns of the cord.—*New York Medical Journal.*

DILATATION OF THE CERVIX UTERI VERSUS DIVULSION.[1]

By AUGUSTIN H. GOELET, M.D.,

NEW YORK.

On May 9th I read, by invitation, before the Medical Society of the State of North Carolina, a paper entitled "The Use of the Dilator and Intra-uterine Stem in the Treatment of Dysmenorrhœa and Sterility," which appeared in the *New York Medical Journal* of May 12th. In this I denounced divulsion, and made the assertion that moderate dilatation, if maintained by the proper use of a stem, was sufficient for all conditions of constriction of the cervical canal. I substantiated this assertion by quoting some fifteen examples selected from my case-book, which show the conditions relieved by this procedure.

To avoid repetition, and in order to take up as little of your time and attention as possible, I will refer you to that paper for more complete details of the operation.

Why do I denounce divulsion? Because it is a dangerous operation and unnecessary. A prominent surgeon recently remarked that he would as soon use dynamite as a divulsor in the male urethra. If divulsion *there* is to be condemned, why should it be considered necessary or safe in the cervical canal? It is neither safe nor necessary. It is irrational in the extreme. The best authorities upon the subject acknowledge its danger, and confess that they frequently find it necessary to repeat the operation. A certain operator admits that there are a number of those operated upon by him, who were only temporarily benefited, and should have it repeated; but they will not permit it. He is an advocate of divulsion, and has invented a dilator much stronger than is generally used. Another operator says he has often been obliged to repeat the operation several times in the same case. The reason for this is obvious. If divulsion or rupture of the constricting fibres, either with or without scarification or incision, is done, and no means adopted to prevent reunion of the severed tissues, even if no untoward consequences follow, recontraction will surely result in many instances, and a repetition of the procedure therefore becomes necessary. Can we accomplish permanent dilatation of a stricture of the urethra, or of any other location, by passing one sound, or a series of sounds, at one sitting, with no further treatment? Can we obtain permanent dilatation by divulsion (even where it is permitted) without proper treatment to maintain it? Then why expect it in the cervical canal? Why look for good results from expedients here, which we know would fail elsewhere? Is this rational?

I do not wish it to be inferred that I believe the same treatment which is applicable to the urethra or strictures elsewhere is proper or sufficient in the cervical canal. The structures are very different. But, to permanently overcome a stricture or constriction anywhere, two things are essential: First, to dilate; and, second, to maintain that dilatation. The principle is the same wherever the constriction occurs, but the method of accomplishing the result varies with the location of the stricture. In the urethra, for instance, gradual dilatation is effective in the majority of cases; but, owing to a difference of structure, it is waste of time in stenosis of the cervical canal. In addition to this difference of structure, a stenosis of the cervical canal is increased by time—the increased weight of the uterus, from chronic congestion, causing an exaggeration of the normal or the original curve of the canal, and a consequent added obstruction. Dilatation alone will not remedy this, or straighten the canal, although it may temporarily relieve the constriction. Divulsion can only increase it by adding to the congestion, from the irritation it provokes. Not only is the curve of the canal increased by time, but a chronic hypertrophy, or thickening, of the lining membrane occurs, which still further increases the difficulty to be overcome. Dilatation or divulsion alone is not sufficient to remove this. Then, to relieve a constriction of the cervical canal, we must not only dilate and maintain the dilatation, but we must correct the abnormal curve in the canal, and overcome or remove the thickened condition of its lining membrane. How to accomplish this, and keep within the bounds of safety, is the question now under consideration.

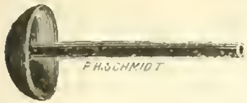
Dilate sufficiently (under an anæsthetic) to overcome the constriction, taking care to do it slowly, and use no more power than is actually necessary; introduce a straight stem of sufficient size to be grasped by the constricting fibres remaining after dilatation; increase the size of this stem as the constriction relaxes, and withal keep the patient prone in bed, and the indication will be fulfilled. Now let us see what we accomplish by this method. The stem maintains and increases the dilatation produced by the dilator, splints up and straightens the organ, and removes the hypertrophy by the constant and increasing pressure exerted by its presence in the canal. At the same time, if properly cannulated, it encourages free drainage from the uterine cavity. Compare this method with divulsion or with dilatation as ordinarily practised. It should be apparent to all that it lacks the element of danger which surrounds the former, and the uncertainty of the latter. But is this all we can say of it? Does it not fulfil every indication required?

The principle involved in the use of the stem may be very simply illustrated. By stretching a piece of rubber tubing over a hard substance larger than its calibre, and leaving it there for a time, its size is permanently increased, because its power of resistance has been overcome. But, you may say, this is not living tissue, and the ultimate result will not be the same. Very true! It will not be exactly the same, for the canal will not remain dilated the size of the stem after its removal. It would not be normal if it did. It will contract, but it will not contract to its former abnormal state, because the conditions which existed there before have been interfered with. The constricting fibres, if any existed, have been kept overstretched for a week, and have lost a part of their power, and remain in a partially relaxed state. If these fibres are muscular tissue, as some believe, this is readily understood, for we know that muscular tissue under certain conditions will remain relaxed. We know, likewise, that a contracted muscle may be permanently relaxed by constant stretching or overstretching; but we know, also, that this power must be constantly applied. In addition to this, the continuous pressure of the stem sets up an alterative action in the lining membrane and the surrounding tissues of the cervix, and in consequence we have an altered condition. In simple stenosis without flexion, the stem acts by keeping the parts overstretched until they become permanently relaxed. But in flexion its action is also that of a splint which corrects the malposition.

It is of the greatest importance in doing the operation to be careful of every detail. As the constriction is usually at the internal os, this is the important point. You must get the stem through the internal os, and you must keep it there by means of a properly adjusted tampon; and to be sure that it has remained in position, you must ascertain by a digital examination, every day, before the tampon is removed, if the cup of the stem is hugging the cervix closely. If it is not, the next tampon must be arranged with more care. You cannot be too particular upon this point. It is for this reason, as well as for cleanliness, that I advise the removal of the tampon and stem every day. As movements of the patient are apt to misplace the stem, she must be kept strictly upon her back or side, and must be allowed, under no condition, either to rise or sit up in bed. And she must be lifted from the bed to the examining table, and back to the bed, for every examination.

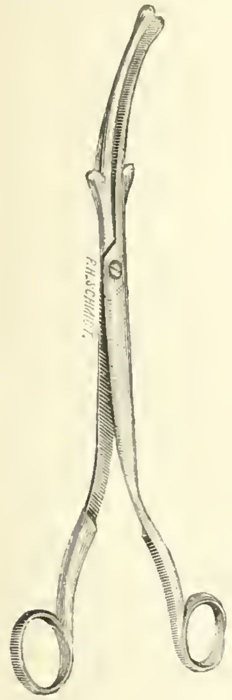
---

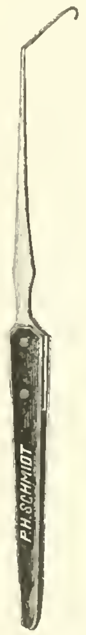
[1] Read by invitation before the New York State Medical Association, third district branch, at Norwich, June 21, 1888.

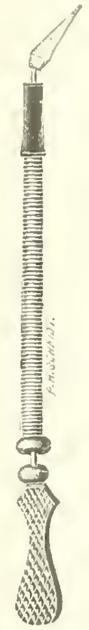


The Sims speculum is considered necessary, because it allows a larger field of operation at the vulva, and the view of the cervix is not entirely obstructed by the cup extremity of the stem while it is being introduced, as is the case with other instruments used with the patient on the back. Its necessity is evident where a flexion exists.

It will be impossible to introduce the stem unless the cervix is fixed by a tenaculum, and if a straight one is used, the shank of the instrument will crowd the stem out of the proper line of direction as the cup nears the cervix, and before the point of the stem enters the internal os. By using the angular tenaculum, as shown in the figure, this will be avoided, and the cup of the stem can be pushed up in position close against the cervix, without even touching the shank of the instrument. The angular tenaculum, instead of pulling against the point and digging into the tissues, as the straight one does, and tearing out, pulls against the curved side of the point, and does not readily tear out. It is decidedly preferable in every instance where much traction is to be made. It is fixed in the cervix with a twisting motion of the hand, similar to the motion used in introducing a corkscrew.







Unless you are particular in the introduction of the stem, a pouching will occur in front of the internal os and a false passage will be made, and of course the constriction cannot be benefited by such a false position of the stem.

In introducing the stem an applicator, with a proper curve near the point, is obviously indispensable. We must get around a corner with a straight stem, and there must be a curve between the point of the stem and the power applied, so that the force exerted will not be in a straight line.

It seems hardly necessary, in this age of antiseptic craze, to warn you that the vagina should be thoroughly washed out with a carbolized solution before any manipulation of the cervix or cavity of the uterus is attempted. And the free use of a four per cent. solution of cocaine over the surface of the vagina and cervix, will add to the patient's comfort after the effect of the anæsthetic has passed off.

It would be a grave mistake to expect a complete cure of every case from the operation alone. In many instances it is only the first step in the treatment, and more care even is necessary in the details of the subsequent treatment than in the operative procedure. More importance should be attached to this part of the treatment than is usually considered necessary. Its value is apt to be underestimated in consequence of the immedate relief which the operation affords, and its neglect will allow failures which reflect upon the operation.

Let me add a note of warning. This is not an operation to be undertaken by everyone indiscriminately. A thorough familiarity with the necessary details is prerequisite to success. While I may have been able to simplify the details so that they may be understood by anyone, there are many points requiring nicety of action which is only to be acquired by experience in gynæcological manipulation. At the same time, let me remind you that it is impossible to foresee exactly what conditions are to be met with in all cases which may happen to come under your observation, or outline their appropriate treatment. Experience has taught me that every case presents some new phase, different often in many important particulars from others with the same symptoms and same general condition, which necessitates a change in the usual methods to meet the required indication.

A STUDY IN PHYSIOLOGICAL ACOUSTICS—PRELIMINARY NOTICE.

By J. A. Maloney,

Washington, D. C.

Many months since, I commenced a line of experiments to obtain, if possible, true graphic delineations of the voice, and had not proceeded far before coming to the conclusion that several things were needful in the mechanism, necessary for such work, as follows :

1st. The material into which the stylus impressed itself should be of such character that intonations or inflections would be preserved. 2d. The diaphragm should be comparatively rigid, and of material different from that formerly used in attempts at this kind of work. 3d. That the mouth-piece should be so constructed that air in the speaking-tube should be partially compressed, without retarding the lip movements of the speaker. 4th. That the same speed of instrument be used for every record.

After months of patient work these requirements were met.

The difficulties attending past efforts in this direction are set out clearly by Clarence J. Blake, M.D., in the *American Journal of Otology*, vol. i., part 1, January, 1879, and part 2, April, 1879. In the latter he compares the value of the graphic and photographic methods for the permanent transfer of waves of sound, and gives undeniable pre-eminence to the photographic representation for purposes of exact research, because of existing defects in the phonograph, but speaks of the still important mechanical difficulties in the way of photography (viz., the preparation of large plates, evenness of motion, etc.), which are, however, not inseparable ; also by Dr. Oscar Wolf, of Frankfort-on-the-Main, in "Arch. Otol.," vol. viii., p. 58, wherein he gives the results of his experiments with an Edison phonograph, using tin-foil as a phonogram. He admits defects in form of instrument used. The greatest obstacle to his success was in the use of tin-foil, which was too yielding. This was manifest in the character of impressions. He gives the letters, A, O, S, R, and says, page 62 : "The consonants B, K, T, F, when spoken alone, give, on account apparently of their weak tone-intensity, no definite 'sound figures.'" I desire to call attention to the difference in conformation between my results and those of Dr. Wolf, and also the letters B, K, T, F, successfully recorded by me. These figures I denominate "Composite Tone Figures," to distinguish them from what is known as "Chladni Figures," formed on vibrating plates of metal, by sand set in motion, due to drawing a violin bow over the edge at different parts of the plate.

In addition to letters recorded, I have taken two words used by some in "Oral Tests" for the deaf, together with responses as follows: "Boy, Hoy, Toy, Fish, Fit, Thish," and by the record show the variation in amplitude of vibrations in the deaf ear, a fact of interest to otologists, going to show clearly a middle ear, or defect in the mechanical branch of the organ of hearing.

I have shown the number of vibrations to inch, entire length of letter or word, total number of vibrations to each, and also depth of imprint. Upon the completion of this, the first branch of my work, I had an assurance of its correctness when I found that no two figures were alike, and that the configurations were in accord with Tyndall's graphic representations of vibrating strings and rods as shown in his illustrations.

Of all letters A has led in number of overtones, as deduced by Helmholtz, Tyndall, and others; in my record you will find it has the greatest number of vibrations —twenty-three to inch, or one hundred and sixty-one vibrations to length of letter (seven inches).

The most difficult word to record and magnify was mamma. This was to me very strange at first, as I thought of it as generally the first word spoken in childhood, and upon investigation, I found the cause in the curious fact that the whole mechanism of phonation, except the lips, is nearly, if not entirely, quiescent during its utterance. This can be readily discovered by placing the index-finger upon the thyroid cartilage, and the thumb upon the side of the neck while sounding it. Another very curious fact is shown in the record of "Thoon and Screech." The "oo" of one and the "ee" of the other, have been considered the representations of "high and low" in audition, yet when combined with consonants, as here shown, the difference in number of vibrations and length of word is very slight. Strange as it may seem, the word "Mississippi," the longest word recorded by me, should give the least number of vibrations of all words or letters used —there were only thirty-two and a half vibrations to a length of three and a quarter inches for the word.

I would call attention to the two words used in testing the deaf, viz., "Boy, Ftish," and the responses made in many cases, "Hoy, Toy, Fit, Thish." The second part of my investigations, which is not yet complete, will, I hope, prove more interesting as an attempt to solve some of the mysteries of audition, by addressing the unexplained workings of the mechanism of the middle ear for clues to abnormities, which may be due entirely to changes in the middle ear hitherto unsuspected.

Fracture of the Symphysis Pubis during Labor.—Dr. Faux has reported the case of a primipara, aged twenty-five, to whom he was summoned during her difficult labor, the presentation being right occipito-posterior. The pelvis was slightly contracted in its antero-posterior diameter. Tarnier's forceps were applied, and traction made for intervals during an hour. As the head reached the perineum, crepitus was distinctly perceived by the operator. Tarnier's forceps slipping, Pajot's were substituted, and labor terminated. At the moment when the head was born the crepitus was again perceived. The head of the child was of normal size, and showed no marks of violence; the child was dead, Faux thought from the long duration of labor (forty-eight hours). The mother had moderate post-partum hemorrhage. On catheterizing her the fracture was plainly felt, and the subpubic tissues were bruised and œdematous. Faux had no opportunity to examine the patient's pelvis before labor. No special malformation was evident. She made a speedy recovery. —*The American Journal of the Medical Sciences*, November, 1888.

Boro-tartrate of potassium is the first remedy for calculus in pelvis of kidney; a weak solution must be used and for a long time, a strong solution being detrimental. (Bartholomew.)

Clinical Department.

PROLAPSE OF THE RECTUM EXISTING FOR TWENTY YEARS.

By FRANK P. HUDNUT, M.D.,

BROOKLYN, N. Y.

M. M——, aged sixty-eight, a fisherman, called to see me complaining of hæmorrhoids. Upon examination I found a large mass, the size of an orange, protruding from the rectum. It was of a bluish color, and divided into three distinct parts. He said that for the last twenty years he had had the most violent pain during defecation, the pain being so severe that he was at times obliged to cry out. He consented to an operation. Calling at his house the next day and giving him an injection, I brought the parts well into view. I proceeded to operate. At his special request no anæsthetic was given. Taking one part of the tumor at a time and cutting a groove around its base, I tied it with a strong ligature as tightly as possible. While doing this the blood was forced out of the mass like water from a sponge. I proceeded with the other two parts in a like manner and opened a small external hæmorrhoid at the same time. He complained of some pain, but was easy in a few minutes. After cutting off the most prominent part of the tumors I found that they could not be reduced, and was obliged to leave them exposed. The parts were dusted with iodol, and pressure was made with a bandage; then one-sixth of a grain of morphia was exhibited and the patient was put to bed. There was considerable oozing from the parts for two days. On the second day they became very fetid, and there was considerable inflammation around the anus. I ordered a poultice and gave quinine, the temperature getting up to 101°. On the third day I detected fluctuation one inch to the left of the anus, and upon opening the abscess about one ounce of pus was discharged. The fetid masses kept up a good deal of inflammation around the rectum, and I decided to hurry matters up by removing the remaining parts by means of Bosworth's nasal snare. This I successfully accomplished in about an hour without losing a drop of blood. The abscess ceased discharging spontaneously and the bowels were moved without pain. The patient was allowed to get up on the seventh day and made an uninterrupted recovery.

SUCCESSFUL PREGNANCY IN HEART DISEASE, WITH SPONTANEOUS PREMATURE LABOR.

By GIDEON C. SEGUR, M.D.,

HARTFORD, CONN.

Early in September, 1888, Mrs. —— was received into my home for treatment. She had been having diarrhœa for several days, attended with nausea and vomiting. The stomach was so irritable that she was able to retain her food but for a few minutes after swallowing it. Twenty grains of sub-nitrate of bismuth, with one drachm of paregoric in an ounce of water was given, and repeated in two hours with good effect. She was expecting to be confined the latter part of November, dating the beginning of her pregnancy from February 20th. I afterward learned, by more careful questioning, that her last menstrual period began January 20th, and continued about one week, and consequently I placed the date of her expected confinement at about the 27th of October.

March 12th, she had an attack of what she called at the time, "indigestion;" when for several weeks she was unable to keep anything upon her stomach, and for about four weeks was confined to her bed. "Morning sickness" continued until early in June, when she experienced "quickening," which was the first that she knew she was pregnant. The physician who had attended her in

March and April, had pronounced that she was not "in the family way." About this time (June) she noticed that her feet and hands began to swell, but she thought little of it; also she found that micturition was more frequent. In July she was much troubled with "canker sores" of the mouth, an increase in the swelling of feet, legs, hands, and face, and frequency of micturition, which was attended with much pain. These symptoms increased gradually until the first of September, when nausea and vomiting, with diarrhœa, were added. At this time she came under my care. An examination of the urine at that time, and repeatedly afterward, failed to reveal any indications of kidney disease. During the succeeding week alkalies were successfully used for the frequent and painful micturition, and cocaine given before eating greatly modified the nausea.

On September 11th, while sitting upon the piazza, she was startled by being addressed by a drunken fellow, who had approached unperceived until close beside her. Meeting the same fellow, while walking in the street a short time afterward, startled her again. That evening she began to have pain in the abdomen and back, which continued more or less all night and increased the next morning. About ten o'clock, when vomiting, she felt something "give way," and there was a gush of water. The membranes had ruptured.

An examination at 6 P.M. revealed a dilating cervix and a vertex presentation. She was very restless and was given thirty grains of chloral in three doses at intervals of twenty minutes. When the expulsive pains began there was marked shortness of breath, and on listening at the heart it gave an almost continuous murmur with accentuations at the time of the pulsations. A few drops at a time of chloroform upon a handkerchief were given by inhalation when the expulsive pains began, which was gratefully received and called for upon the beginning of subsequent pains.

A male child was born at 8.30 P.M., fairly well nourished but quite weak, and comparing in development to a seven-months' fœtus. One drachm of Squibb's fluid extract of ergot was given. The placenta was delivered readily in about twenty minutes. During this time a tendency to cough was developed, the breathing was shallow and rapid, and a feeling of prostration experienced. A cup of warm milk and tea was given; the toilet was made and binder applied. The uterus was well contracted. A smaller dose of ergot (gtt. xv.) was given later, but being followed soon after by vomiting, which increased the dyspnœa, no more medicine of any kind was given during the night. The frequent desire to pass water continued during the night, and the patient was allowed to sit up each time. The rapid respiration continued all night, gradually decreasing in frequency, but not becoming natural for two days. During the following week micturition occurred, upon an average, every two hours.

Five minims of tincture of digitalis were given three times a day; also a two-grain pill of citrate of iron and quinine. On account of the irritable condition of the stomach the only form of nourishment given during the first twenty-four hours was kumyss, of which three or four ounces were given every three or four hours: it was greatly relished by the patient and retained.

Although efforts were make to stimutate the secretion of milk, there was only a very little obtained. The child made feeble efforts at nursing the first few days, but the very small secretion ceased and artificial feeding had to be resorted to. On account of the weak condition of the baby, it was thought best to tax its strength no more than was necessary. It was freely anointed with sweet-oil, wrapped in blankets, and placed in a basket with three hot water-bottles—one on each side and one at the feet—in a room, the temperature of which was not allowed to fall below 80° F. night or day for the first three weeks. During the first forty-eight hours it was placed to the breast at intervals of six hours; when milk appeared every three hours. Efforts at suckling were quite short and feeble. A little cool water was given the child at intervals during each day, and upon the third and fourth days he was given a teaspoonful of half milk and half water. The mother's milk was drawn and fed to the baby, and efforts to promote the secretion of the milk by hot applications, lubrications, castor-oil, etc., were used without success. The milk gradually decreasing rather than increasing in quantity (I was never able to get more than ʒ j. from either breast at any one time), recourse was had to feeding with the bottle, and peptozenic milk powder was used in the preparation of the food, beginning with ℥ ss., and gradually increasing the quantity until now, at the end of the fifth week, he is taking ℥ jss. every two hours.

The mother is now free from all disturbing symptoms of the heart disease, though the imperfect action of the valves can be readily perceived upon auscultation. She has had no trouble with digestion, eating many articles of food that she had shunned for years, and can be pronounced none the worse for her pregnancy. About three weeks after confinement she had, what at any other time would have been called a menstrual period, differing but little, if at all, from her experiences when regularly "unwell."

The special points of interest to me in this case are:

1. That a woman with valvular disease of the heart can carry a fœtus in utero until it attains a viable age, pass through the trials of premature labor, and be apparently none the worse for it.

2. Spontaneous premature delivery occurring after viability was attained.

3. That a weak, premature infant, of not more than 236 days (the time from the *beginning* of last menstruation to the day of birth was 236 days), can be kept alive by the careful use of ordinary means, particularly in keeping it warm, and also when obliged to use artificial food.

The child at birth weighed four and a half pounds; during the first week it lost a half pound, but each succeeding week has gained a half pound, until now, at five weeks, it weighs six pounds. Had the child remained in utero it would now be approaching the time of its birth. Its chances seem to me to be as good to-day, if not better, than if it had not been prematurely born.

EPISTAXIS: ITS TREATMENT BY OLEUM ORIGANUM.

DR. LOUIS FISCHER, of New York, writes: "My attention having recently been called to the astringent effect of the above remedy, I thereupon used it in the treatment of epistaxis with very gratifying results.

"Nor was its effect shown in any specific case, for I took occasion to use it in every case that presented itself, in the same manner as I would have used our other internal remedies. With a view of benefiting others in the same way as my patients were benefited, I hereby recommend it to the profession.

"The literature on this drug is totally obscure, it therefore took some time to learn the real effect of it.

"I have commenced by giving gtt. v., t.i.d., an hour after meals, and increased the dose gradually until in one case I gave gtt. xii., t.i.d.

"Owing to the disagreeable smell and taste (oleum origanum being one of the turpentine series) I gave it in the form of an emulsion or in gelatine capsules."

PROFESSOR to Medical Student—"How would you treat post-partum hemorrhage?" Student—"I would tie the post-partum artery." That student is now carrying the hod.—*Nashville Medical Journal.*

This is a mistake. That student is now practising his profession successfully in a town in Northern Indiana. His specialty is obstetrics, and every woman for miles around is morally certain that no child can be successfully ushered into this wicked world without his assistance. —*Indiana Medical Journal.*

Progress of Medical Science.

Operative Treatment of Peritonitis.—Professor Luecke has reported the following case: A youth, aged sixteen, drank a glass of beer, and soon afterward felt severe abdominal pain. He was admitted into hospital with all the signs of acute peritonitis; temperature 106° F. The abdomen was opened the same evening, and half a litre of pus removed; it was then washed out with weak sublimate solution, and a thick drainage-tube was placed in Douglas' pouch. The patient went on well for six weeks, when a subphrenic abscess developed on the right side, which soon broke into the pleural cavity. Resection of the seventh rib was performed, and drainage instituted with perfect success. There was doubtless a latent intestinal ulcer with first perforative peritonitis, and subsequently localized peritonitis, which broke through the pleura. Dr. Heuser, of Barmen, has lately operated in three cases of perforation of the vermiform appendix. Two of the operations were successful, but in the third there were metastatic abscesses in the liver, which soon caused death. In each case the abscess was sharply defined, though without extensive adhesions. Dr. Heuser thinks that many such cases which end fatally might be saved by surgical treatment. Professor Czerny, of Heidelberg, operated in perforative peritonitis in an obscure case; a large quantity of odorless gas escaped, and the stomach was found adherent to the liver and anterior abdominal wall. The intestines were normal. Unfortunately no attempt was made to free the stomach, and the patient died on the fourth day. On post-mortem examination there was found a gastric ulcer and subphrenic peritonitis. An odorless gas in such cases indicates perforation of the stomach; a fetid gas intestinal perforation.—*The British Medical Journal*, September 15, 1888.

Treatment of Enuresis by White Sumac.—Dr. Unna, after three years' experience, recommends the fluid extract of the bark of the root of the sweet sumac (*Rhus aromatica*) in the nocturnal enuresis of children. The drug has also been of benefit in hemorrhage of the bladder, uterus, and rectum, and in atonic diarrhœa. In the enuresis of children it acts as a specific, but its effects are not permanent, the paresis of the sphincter muscles of the bladder returning soon after the remedy is discontinued. It should therefore be used in conjunction with other means, such as training to a habit of regularly emptying the bladder, cold baths, douches, cool bedding, etc., and then be only gradually withdrawn. For children of two years and under, Dr. Unna gives five-minim doses of the fluid extract in the morning and at bedtime; two to six years, ten minims; and for older children fifteen minims twice daily.—*Denver Medical Times*, October, 1888.

Human and Animal Blood.—Dr. Cevera asserts that human may be distinguished from animal blood by the following method: If the blood be mixed with a little bile, small crystals are formed which are of different shapes in different species of animals. In man, it is claimed, they are right-angled prisms; in the horse cubes; in pigs right-angled prisms very similar to those seen in rhomboids; in sheep rhomboidal plates; in dogs the same as seen in human blood; and in chickens more or less regular cubes.

Chloride of Zinc for Intra-uterine Use.—Following the recommendations of Rheinstaadter, Dr. Brose has employed chloride of zinc for certain uterine diseases, such as endometritis, subinvolution, erosions, and even gonorrhœa. He claims excellent results from this method of treatment. A solution of equal parts of chloride of zinc and water is used. A pledget of cotton wrapped on an aluminum sound is introduced through a Fergusson speculum. After the size and direction of the uterine canal is ascertained by the sound, the cotton is dipped in the solution, introduced into the uterine cavity, gently pressed in various directions, and withdrawn. The procedure must be completed quickly, for the uterus, from the effects of chemical irritation, contracts very rapidly, and if the contraction should occur before the internal os is passed, in most cases the effort to reach the fundus must be abandoned. The fluid which flows from the uterus after cauterization must be caught up or washed away in order to prevent it affecting the vagina. This cauterization is repeated once or twice a week, and can be performed in the physician's office. Many patients after cauterization have no pain. A few suffer from uterine colic. The author has never seen unfortunate results follow this plan of treatment. Stenoses were not observed. If fresh inflammatory processes exist in the neighborhood of the uterus this procedure should not be undertaken; with old inflammations, too, one must be very careful. That the mucous membrane of the uterus after cauterization is not atrophied, but returns to its normal condition, is proven by the fact that many cases conceive immediately after the termination of treatment.—*Archiv für Gynäkologie.*

Hip Disease from an Unusual Cause.—Mr. Henry G. Rawdon reports, in the Liverpool *Medico-Chirurgical Journal* for July, 1888, a case of hip-disease with unusual causation. The boy was six years old, and had been well up to six weeks before admission to hospital, when he was suddenly seized with a succession of convulsions alternating with periods of unconsciousness, which extended over a period of three weeks. At the end of this time it was found that the boy was unable to walk or to use in any way the right leg. On admission to hospital the boy presented well-marked symptoms of hip-disease. The head of the femur was resected, and was found to be only slightly diseased, this fact indicating that the disease was secondary in its origin. The incision gave exit to a large amount of pus. The joint did well, but the boy did not improve, some sinuses remaining in the high. These were explored, and at the bottom of one a swelling could be detected. On making firm pressure on this a large mass of solid fecal matter was expressed. The sinuses were then thoroughly washed out, and the boy made a slow recovery. The author believed that this curious occurrence was to be explained by an attack of perityphlitis which had given rise to suppuration involving the walls of the cæcum causing perforation. Pus had doubtless formed and passed through the pelvic peritoneum until it reached the obturator foramen. Having passed through this it would be likely to follow the path of least resistance and enter the joint under the transverse ligament, along with the intra articular vessels. The mass of fecal matter in the thigh he was inclined to regard as of gradual accretion, probably taking place some weeks after the resection, although it might possibly have been forced down between the muscles during a single straining effort at defecation.

The Best Internal Remedy in Laryngeal Diphtheria.—Perhaps the most useful internal remedy is mercury. Empiricism has often praised calomel in small and large doses. My acquaintance with mercury in this connection is not at all new. More than four years ago I published a number of cases which got well under its use, at the same time that Dr. Thallon, of Brooklyn, published an article on the same subject. Since I have employed it, I prefer the bichloride; my conviction of the utter uselessness of internal medication in laryngeal diphtheria, so-called pseudo-membranous croup, is thoroughly shaken. Until about six years ago I felt certain of a mortality of ninety or ninety-five per cent. of all the cases not operated upon. These figures were not taken from small numbers, for I compared those I found with my own. The latter are not a few neither; for within the last thirty years I have tracheotomized nearly 600 times, have assisted at as many more operations, and have seen at least 1,000 cases of laryngeal diphtheria which were not operated upon at all. During the last six years I have seen no less than 200 cases, perhaps many more. Among them recoveries have not been rare at all, at all ages. from four months upward. The uniform internal medication consisted in the administration of a dose of the bichloride every hour. The smallest daily dose ever given by me in the beginning was 15 milligrammes, ¼ grain, to a baby of four months; this was continued a few days, and the dose then somewhat diminished. Half a grain daily may be given to children of from three to five years, for four or eight days or longer. The doses vary from one-sixtieth to one-thirtieth. They require a dilution of 1 in 6,000 to 10,000 of water or milk. There is no stomatitis, gastric or intestinal irritation is very rare. It occurred in a few cases, but then it was found that the dilution had not been sufficient, 1 in 2,000 or 3,000 only. If ever it exist, small doses of opium will remedy it. The benefit to be derived from the remedy depends greatly upon the time of its administration. Tracheotomy or intubation is required, as a rule, after some days, and can often be avoided if mercury be given in time. If the operation become necessary after all, the treatment must be continued diligently. Never have I seen so many cases of tracheotomy getting well, since 1863, as when the bichloride was being used constantly in 1882, and the five subsequent years. Nor am I alone with these favorable results. There are dozens of practitioners in New York City with whose methods and results I am well acquainted, some of whom are connected with me in some capacity or other, who confirm the above statements.—DR. A. JACOBI, *British Medical Journal.*

INCISION OF GANGRENOUS LUNG.—An interesting case of gangrene of the lung was reported at the first meeting of the Clinical Society by Dr. W. Pasteur. The patient, a boy aged seven, was admitted with a history of acute illness in which he had coughed up some bright blood, and it was said that since then his breath had been very offensive. The physical signs were those of a cavity at the right apex, the rest of the lung being pneumonic. He coughed up from two to four ounces daily of a watery, stinking fluid, mostly saliva. The cavity was incised at the anterior extremity of the second right intercostal space, an inch from the sternum, and large quantities of gangrenous lung and putrid fluid were expelled through the wound. A counter-opening was made in the sixth space, a drainage-tube was put in, and for a week all went well; but the boy then failed rapidly, and died in three days with pericarditis. At the post-mortem the œsophagus was found adherent to the right bronchus, and a sinus communicating was evidently the cause of the gangrene. It was suggested that the child might have swallowed a foreign body, and thus set up the œsophageal trouble. There was a large gangrenous cavity in the apex of the right lung.—*London Cor. New York Medical Journal*, November 3, 1888.

FILARIOSIS.—Dr. Lancereaux has recently contributed an important monograph, entitled "La Filariose." to the Académie de Médecine (*The British Medical Journal*). He gives full credit to the labors of Drs. Mackenzie and Manson. The term "filariosis" he applies to the entire group of pathological conditions resulting from infection of the organism by the *filaria sanguinis hominis*, including lymph-scrotum, chyluria, and chylous dropsy of the peritoneum and tunica vaginalis testis. Dr. Lancereaux has seen some cases in Paris, and read two clinical reports as part of his paper. The first patient was a law student, aged twenty-three, and very sickly; he was a native of the Isle Réunion, came up to Paris in 1884, and began to suffer from lymphatic varices in the groin in 1885. Chyluria and dilatation of some lymphatic vessels in the arms followed; the scrotum was not affected. A finger was pricked, and the blood which exuded was found full of filariæ moving actively. In the second case, the patient was also a law student, in Paris, who left his native island, Hayti, in 1866. Severe chyluria set in on his return home a few months later; in January, 1888, after he had come back to Paris, he had hæmato-chyluria. At present the urine passed on rising is always more or less chylous, though no blood is now mixed with it; that passed in the afternoon is often normal; urine passed at midnight presents the maximum of chyle. At ten minutes to nine one evening the patient's blood was examined, and no filariæ were found; a quarter of an hour later the finger was again pricked, and nine filariæ were detected in the blood. A physician, now at Beauvais, who practised for sixteen years at Hayti, informed Dr. Lancereaux that he was seized with chyluria when thirty-five years old, during the height of the hot season, and much fatigued by professional work. It lasted for several days; a few more attacks followed. After living a few months in Europe the patient had no recurrence of chyluria for six years. Three times during the period he has been established at Beauvais he has had a transitory attack of chyluria. On every occasion it followed night work in very cold weather.

THE GROWTH AND DEVELOPMENT OF THE TONSILS.—The subject of the growth and development of the tonsils has just been carefully studied by Retterer. His statements are to the effect that the tissue elements of the tonsils proceed both from the epiblast and from the mesoblast, the former supplying the cellular elements, the latter the connective-tissue septa, the blood-vessels, and probably also the lymphatics; while in most glands the basilar layer of the epithelium forms the whole of the involution, in the tonsils, the whole thickness of the epithelial investment proliferates. In most glands, again, the primitive invagination remains as the excretory canal, but in the case of the tonsils the primitive involutions form the crypts or diverticula lined by a layer of pavement epithelium. Another curious point is that the tonsils are homologous with the bursa Fabricii of birds, both as to their origin, development, and structure. During the greater part of their existence the epithelial elements of the tonsils preserve the general form and characters of the basilar cells of the epithelium, but toward the close of life they disappear by fatty degeneration, and alveoli make their appearance. In the adult the lymphatic system occupies the whole thickness of each lobule; it forms a net-work of canals lined with endothelium. The walls of these lymphatics are everywhere perfectly closed, and do not open into the connective-tissue reticulum either by stomata or by open extremities. The memoir is accompanied by many well-executed drawings of the tonsillar region of the horse, pig, dolphin, cat, dog, rabbit, and other animals, as well as of man.—*The Lancet.*

ELECTRICAL TREATMENT OF INTESTINAL OCCLUSION.—At a recent meeting of the Academy of Medicine Dr. Larat read a note on the treatment of intestinal occlusion by electricity. According to the author, galvanic electricity of the intestine deserves to be employed in all the cases of occlusion where medical means had failed, and where the obstacle has become insurmountable by the action of purgatives. Moreover, purgatives are useless when the intestine is impermeable, and become injurious in exciting vomiting, which would aggravate still more the condition of the patient. Dr. Larat says that it is essentially of importance not to lose time, and that electricity should be employed as early as possible; in the first place, the procedure would have a better chance of success; and, secondly, if it should fail, surgical intervention would still be possible and have some chance of success. One application of electricity only is often powerless to obtain movement of the bowels; four or five sittings on an average are necessary, and at intervals of several hours. Of sixteen cases, Dr. Larat removed the occlusion of the intestine by electrization in ten.—*The Lancet.*

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, November 17, 1888.

A SCIENTIFIC ATTACK ON THE CORSET.

THE crusade against lacing and the use of corsets has never been taken up very warmly by the medical profession. Perhaps this is because the doctors' wives and doctors' daughters are continually showing them that lacing, like tea-drinking, is a practice which will be followed despite all that science may disclose. Perhaps, too, it is because the attacks of reformers upon the corset have been of a too hysterical and sweeping character, and based upon general grounds rather than any carefully collected observations.

Dr. Kïanovsky, of St. Petersburg, has, however, lately presented an array of facts physiological and pathological telling severely against the corset (*Wratch*, Nos. 20 and 21, 1888; *London Medical Recorder*, October 20, 1888).

The observations of his predecessors in this line of investigation are first given. Professor Flower's work on "Fashion in Deformity" is rather a scientific than a critical study of the question. Professor Lesshaft, in 1884, however, made some observations on school-girls and found spinal curvatures far more often in boys than in girls. This he attributes to the use of corsets by the latter, a conclusion which is, however, a *non sequitur*, considering how many other factors are at work. Professor Lesshaft, with more reason, thinks that the use of corsets weakens the osseous and muscular structures of the trunk, and causes protuberant bellies and lax abdominal walls. Perhaps if young women knew that corsets which constricted the waist would eventually give them an obtrusive abdomen they would be more careful in their lacing. According to Dr. Kïanovsky, "masses of women (in institutions for young girls, among certain Caucasian peoples, etc.), feel ashamed to have full or large mammæ, and strive as much as possible to acquire flat, 'youthful' breasts; hence, during the period of development of breasts the women not only lace themselves tightly in stays and bodices, but, in addition, sleep on their breasts with some hard object (book, etc.) below." Professor Bouchut draws attention to the fact that pressure of stays on the intercostal spaces in tight-lacers suffering from intercostal neuralgia, may give rise to paroxysms resembling angina pectoris. Meyer states that tight-lacing decidedly manifests an injurious influence on the eye, in consequence of congestion resulting from obstructed reflux of blood from the head along the jugular veins. Almost every handbook of pathological anatomy describes a peculiar, more or less deep, groove on the surface of the liver, which is very often found on the post-mortem examination of female bodies, and which is caused by tight lacing.

According to Professor N. Kïanovsky, of St. Petersburg (*Handbook of Special Pathological Anatomy*, p. 204), "the hepatic capsule adjacent to the grooves proves to be considerably thickened from chronic inflammation, while the hepatic tissue itself at such spots is dense, atrophied to a more or less considerable depth, and sometimes even void of any glandular elements." Professor V. A. Manassein has for many years drawn the attention of his students to an important *rôle* appertaining to stays (and tight petticoat bands) in the etiology of gall-stones. His observations are supported by Dr. Rotter (*Deutsche med. Wochensch.*, February 14, 1884), according to whose researches on gall-stones, of 1,034 necropsies at Munich the stones were present in men in 3.9 per cent. of the whole number, and in women in 9.9 per cent.; in as many as forty per cent. of the female cases, simultaneously with gall-stones, there were found grooves and constrictions caused by stays. An important work recently published by Professor Marchand (*Deutsche med. Wochensch.*, March 22, 1888) throws a strong light on the mechanism of the formation of gall-stones in tight-lacers. Dr. W. J. Collins' experimental researches (*The Lancet*, March 17, 1888, p. 518) similarly elucidate pretty well why "deficient bile, dyspepsia, sickness, constipation, clayey stools, headaches, chlorosis, debility, may form a natural sequence" of tight-lacing.

Dr. Arini has reported a case showing that tight-lacing may cause wandering liver.

Drs. Graily Hewitt, Meyers, and Helene Belts assert that tight-lacing may cause displacements and flexions of the womb. Neftel's experiments showed that thoracic and abdominal compression cause anæmia. Schuter found that a lasting compression of the chest could cause albuminuria.

Kïanovsky, experimenting on fourteen habitual tight-lacers, found the average decrease of vital capacity of the lungs, when corsets were worn, to be 357 cubic inches. The strength of inspiration and expiration was decreased also, and the respiratory excursion of the chest. Hence he concludes that the corset dooms the wearer to oxygen starvation. He also found a lowering of blood-pressure and "arterial anæmia" as a result of the lacing.

The list of ills which the corset brings with it may here be repeated for the benefit of the fair and willing victims of the fashion:

Local inflammation of the liver.
Gall-stones and biliary colic.
Wandering liver.
Protuberant abdomen and enteroptosis.
Prolapse and flexious of the womb.
Lateral curvatures of the spine.
Anæmia, chlorosis.
Dyspepsia.
Diminished lung capacity and oxygen starvation.
Intercostal neuralgia.
Weak eyes.
Bright's disease.

This is a list that ought to convey dismay to the hearts of corset-makers and corset-wearers. But we suspect that women will continue to wear stays, and will answer to the complaints of science that the life of woman is, despite her dress, longer than that of man.

A REACTION AGAINST ANTISEPTICS.

THE movement against the use, except in a limited degree, of antiseptics, or, as they are now called, antimycotics, has received strong support from the investigations of Dr. E. Senger (*Deutsche Med. Zeitung*, No. 43, 1888), who shows the dangers of strong antimycotics in surgery, and the inutility of mild ones. Dr. Senger clearly states his position in a discussion following his paper (*London Medical Recorder*): All operations, he said, might be divided into two groups. In the first group strong antimycotics were applied, and these were the less dangerous operations. In the second group weaker solutions, particularly of boric and salicylic acid, were used. Antiseptics were introduced with the intention of killing any fungi that might have settled in the wound; in short, to disinfect. Antimycotic treatment was supported by the classical researches of Koch. Perhaps, however, it would be better, from the practical surgeon's point of view, to establish a basis by means of experiments in the disinfection of pus cocci. No doubt strong antimycotic solutions, such as sublimate and carbolic acid, destroy the staphylococcus aureus, but the weaker solutions do not effect this, though where they are employed there is a greater, nay a fatal, danger from a faulty antisepsis. Just in such cases in which strong solutions should be applied, they are inadmissible on account of the danger of poisoning; and again they are applied when they are much less needed. The theory and practice do not harmonize. To kill a pus coccus that has fallen into the abdominal cavity, washing with a four per cent. solution of boric acid is not sufficient, for you could let the man lie immersed in such a solution for five days and not accomplish that object. The same may be said of salicylic acid. Yet the results of operations in the abdominal cavity are excellent, and Senger believes that it is only necessary to wash the wound with sterilized water. He lays no particular stress on the common salt solution. The disinfection of a living tissue he considers to be impossible. Either the tissue is free from germs, in which case there is no need of an antimycotic, or it is infiltrated with pathogenic fungi, in which case it is impossible to destroy the fungi without at the same time seriously injuring the tissue. Disinfection answers admirably on dead objects, but in the case of living organs more importance must be attached to vital energy. Did not Virchow, at a time when it seemed as if the whole of pathology depended on pathogenic bacteria, especially direct attention to the conflict between the cells and bacteria? Surgical examination showed this in wounds in connection with syphilis, tabes, diabetes, and other exhausting diseases, so that, in spite of the strongest antiseptics, it was impossible to prevent purulence and purify the wound, because the energy of the cells had much abated and disinfection was impracticable. By all means let dead objects, such as instruments, the operating-room, etc., be thoroughly disinfected, but after the first incision no antimycotic whatever should be used. In how far these theoretical demands can be met in practice must be decided by those who have great opportunities of practice. The latter alone can determine the cases in which antimycotics are indispensable; but the general rule of avoiding their use should be observed.

LAPAROTOMY FOR GUNSHOT WOUNDS OF THE INTERTINE.

DR. H. C. DALTON, of St. Louis, reports a case of gunshot wound of the stomach and liver, in which laparotomy was successfully performed. The patient, a man twenty-two years old, was shot with a pistol of thirty-eight calibre at a distance of four or five feet. He was driven a mile and a half after the injury. The abdomen was opened, and two holes found in the stomach; the left lobe of the liver had been ploughed through by the bullet, which, however, could not be found. The liver and stomach were sewed up, and the abdominal cavity closed. The patient, after nearly losing his life from a hypodermic injection of grain $\frac{1}{120}$ of hyoscyamine given to relieve a distressing hiccough, finally recovered.

Dr. Dalton gives a table of sixty-nine cases of abdominal section for gunshot wounds, with twenty-seven recoveries and forty-one deaths.

Before the operation of laparotomy was introduced the mortality was ninety-two per cent.

Dr. Dalton states that he is the first to successfully suture the liver in such cases as these.

THE ANNIVERSARY OF THE ACADEMY, AND THE NEW BUILDING.

THE plan which has been adopted by the New York Academy of Medicine of having annual addresses to which the public are invited, is seen every year to be wise and beneficial. The addresses have been given by representative members of our profession, and have been creditable to the speakers and to the Academy.

One cannot but feel, however, in inviting lay guests to the hard board seats and narrow walls of the Academy, that the impression given of the material resources of our profession here cannot be a favorable one. The physicians of New York number between two and three thousand; the Academy numbers nearly a thousand members, and includes the most prosperous portion of our medical workers. The Academy ought to have better quarters, and to receive public guests in a less barren, white-walled, inacoustic audience-room. Distinguished laymen must find it hard to get *en rapport* with medicine while seeking for sedentary comfort on a perforated board, dodging draughts, or stifling in a heated mixture of pulmonary exhalations and alleged atmospheric air.

The Academy anniversary discourse suggests, as has already been seen, that the functionaries of that learned institution ought to take some early action in the matter of a new building. Reports agree that quite enough money has been raised to make a start, and it will be vastly easier to raise more money when a building has been begun, and something tangible can be shown to those of whom donations are asked. It is only fair that by the application of the bond system those who come after us and who will enjoy the present generation's work be given an opportunity to pay for part of it.

THE MORTALITY OF PNEUMONIA.

The mortality of pneumonia, it has recently been alleged, is higher proportionately now than it was fifty years ago before venesection had been abandoned. The figures upon which this assertion is made were put forth by Dr. Hartshorne, of Philadelphia, last February, and were discussed in this Journal of May 19th. In the November issue of the *University Medical Magazine* Dr. William Osler takes up the question and contradicts the views of Dr. Hartshorne. Dr. Osler has secured statistics of the pneumonia mortality for a series of years at the Montreal General Hospital, the Pennsylvania Hospital, and the Charity Hospital at New Orleans. At Montreal the statistics were available since 1853. In the decade 1853-63 there was a mortality of 16.2 per cent.; decade 1863-73, 16.1 per cent.; decade ending 1883, 23.7 per cent.; and in the years 1883-87, a mortality of 20.3 per cent; a total of 1,012 cases with 206 deaths, equal to 20.4 per cent. In Charity Hospital, New Orleans, the death-rate has been as follows:

	Per cent.
1830-39	44.6
1840-49	35.3
1850-59	32.2
1860-69	43.9
1870-79	40.2
Average	38.01

As to the Pennsylvania Hospital, Dr. Hartshorne, in his paper before the College of Physicians of Philadelphia, quoted the mortality in three years of the 4th, 6th, and 8th decades to show a progressive increase in the death-rate, which might possibly be attributed to changes in the methods of treatment. There is indeed an increase, as shown in Table I., but Dr. Osler shows in Table II. that four other periods of three years in successive decades indicate that the mortality "has, if anything, been reduced."

Table I.

	Per cent.
1845-46-47	16.0
1855-56-57	25.4
1865-66-67	24.1
1875-76-77	39.2
1885-86-87	36.1

Table II.

	Per cent.
1848-49-50	37.9
1858-59-60	21.2
1868-69-70	22.8
1878-79-80	32.7

A combination of the two tables, however, does certainly indicate an apparent increase in the mortality-rate.

In the other tables, also, the figures seem rather to show an increase than otherwise. The other statistics of mortality-rates under Laennec (10 per cent.), Diett (19.5 per cent.), Grisolle ($15\frac{11}{12}$ per cent.), are also to be taken into account. Bennett asserts that the old death-rate from pneumonia in the army and navy was $7\frac{9}{13}$ per cent., while the modern death-rate is $14\frac{2}{7}$ per cent.

The death-rate in the United States Army is said to have been less during venesection times than later, viz., 1 in 11.5 as against 1 in 6.67.

All of the foregoing show that figures are not very trustworthy, and that the question of increased mortality-rate in pneumonia is still not settled. The probabilities, however, are strongly in favor of an increased rate in general hospitals, at least. This may not indicate a worse system of therapeutics, however, but rather that patients have a less degree of vital resistance, owing to an increase of poverty and alcoholism. In this connection, also, the communications upon the general question by our esteemed correspondents in this issue will be read with interest.

A SAFE ANTISEPTIC SOLUTION.

The idea that combinations of antiseptics are more powerful than the single chemicals is not a new one, but any practical application of the idea has not, so far as we know, had any wide adoption.

Dr. Emil Rotter, in an article in the *Centralblatt für Chirurgie*, No. 40, 1886, brings up the subject again and offers an antiseptic solution which he claims is very powerful, yet not toxic to any dangerous extent. The solution that he desired to obtain was to have, he said, the following characteristics: It should contain no poisonous agent in quantity sufficient to cause any harm if absorbed; it should be non-irritating and easy to keep; it should be clear and free from odor; it should mix easily with ordinary water; it should be so compounded that the essential constituents could be carried as a powder or pastille.

The following was the result of his experiments:

℞.	Corrosive sublimate	0.05 (1 to 20,000, gr. j.)
	Sodii chlorid	0.25 (gr. vss.)
	Acid. carbolic	2.00 (gr. xxx.)
	Zinci chlorid.,	
	Zinci carbolat ãã	5.00 (ʒ j½.)
	Acid. boric	3.00 (gr. xl.)
	Acid. salicylic	0.60 (gr. x.)
	Thmyoli	0.10 (♏ ij)
	Acid. citric	0.10 (gr. ij.)
	Aquæ q. s. ad	1,000.00.
M.		

This solution was tested in both laboratory and surgical cases. In the laboratory he found it to have a more potent effect on pyogenic microbes than sublimate in solutions of 1 to 1,000.

He gives a list of twenty-three, mostly minor, surgical cases in which it acted most efficiently.

THE TITLE OF DOCTOR.

In olden times the title of doctor was considered justly as an honor, and an evidence of sound education and academic training.

The extraordinary fondness in this country for titles of all kinds, especially those of doctor, professor, and colonel, or some military equivalent, have taken away all prestige from the name. The druggist at the corner is a doctor, the chiropodist is a "professor," the advertising columns of the newspapers are emblazoned with pictures of long-haired "doctors" and "professors."

To a man who has been a groom the bestowal of the title of "doctor medicinæ" no doubt still confers an honor; but, on the whole, the title has become rather a trade-mark and a convenient means of unobtrusive advertisement rather than a badge of distinction or evidence of scholarly attainment.

There seems to be a growing feeling that, after all, the title of "mister" is as noble a one as a gentleman needs or can desire.

Says *The Lancet*, regarding this matter: "There is one title that is highly honorable, and is almost now a distinction among medical men who feel their own strength and rest on their consciousness of being masters of their art—the good old title of 'mister,' which some of the best men in the profession find ample for all social and professional purposes. It is certainly infinitely more honorable than any unacademic or unwarranted use of the title of 'doctor.' And we see many indications that this view is shared by the profession, and by many who think they have a right by courtesy to something more."

News of the Week.

New York Obstetrical Society.—Officers elected for 1888-89: *President*, Dr. H. T. Hanks; *First Vice President*, Dr. Bache Emmet; *Second Vice-President*, Dr. H. D. Nicoll; *Recording Secretary*, Dr. Egbert H. Grandin; *Assistant Recording Secretary*, Dr. A. M. Jacobus; *Corresponding Secretary*, Dr. H. M. Sims; *Treasurer*, Dr. J. L. Morrill; *Pathologist*, Dr. H. C. Coe.

A New Journal has been started in London, *The Illustrated Medical Journal*. It is to give a colored lithograph weekly, and copious illustrations are promised in the text.

Gum Chewing.—Our esteemed and conservative contemporary, *The New York Medical Journal*, has taken a great responsibility upon itself, for, according to the Maryland *Medical Journal*, it is inclined to endorse the habit of chewing gum.

Poisoned by Cheese.—Over two hundred cases of sickness, caused by eating cheese, have been reported to the Ohio State Board of Health, within a few months, the towns of Urbana and Mansfield contributing about fifty cases each. Grave symptoms, even to complete syncope, appeared in some cases, but there were no deaths.

Execution by Electricity.—The Committee of the Medico-legal Society, composed of Drs. Frank Peterson, R. Ogden Doremus, Frank H. Ingram, and J. M. Bleyer, made a report last Wednesday evening, in which the following description was given of the proposed methods of executing criminals by electricity:

"The electric current, in passing through the body from one pole to another, undergoes more or less diffusion through the tissues. A current passing from the top of the head to the small of the back will be diffused throughout a great part of the brain, and all of the tissues of the neck. The medulla oblongata—a part of the brain which is most vital—together with all of the great nerves of the neck and the spinal cord, which exercise jurisdiction over the movements of the lungs and heart, will be thoroughly permeated by the current applied in this way. As the seat of consciousness is in the brain, and particularly in the cortex of the cerebrum, it is clear that this faculty of the mind will suffer at once if the current be sufficiently strong. The electric stream flows from the positive to the negative pole, and there might be some possible advantage in placing the positive pole on the vertex of the head, nearest the centre of consciousness, although death in any case will be instantaneous. After mature deliberation, we recommend that the death-current be administered to the criminal in the following manner:

"A stout table covered with rubber cloth, and having holes along its borders for binding, or a strong chair, should be procured. The prisoner, lying on his back or sitting, should be firmly bound upon this table or in the chair. One electrode should be so inserted into the table, or into the back of the chair, that it will impinge upon the spine between the shoulders. The head should be secured by means of a sort of helmet fastened to the table or back of chair, and to this helmet the other pole should be so joined as to press firmly with its end upon the top of the head. We think a chair is preferable to a table. The rheophores can be led off to the dynamo through the floor or to another room, and the instrument for closing the circuit can be attached to the wall.

"The electrodes should be of metal, not over one inch in diameter, somewhat ovoidal in shape, and covered with a thick layer of sponge or chamois-skin. The poles and the skin and hair at the points of contact should be thoroughly wet with warm water. The hair should be cut short.

"A dynamo generating an electromotive force of at least three thousand volts should be employed. Either a continuous or alternating current may be used, but preferably the latter. The current should be allowed to pass for thirty seconds."

The Society was not prepared last night to take action upon the report, because the committee took them by surprise. The report was not expected until the December meeting, and so it was laid on the table until that time to admit of all being present.

The law provides that executions by electricity shall take place only in Sing Sing, Auburn, and Clinton. New York City murderers will be executed at Sing Sing.

The Pasteur Institute, Paris.—The Pasteur Institute was opened, November 14th, in the presence of President Carnot. Pasteur received an ovation from the people present. In an address, he expressed his thanks for the support he had received in fulfilling a humane task.

Woman's Hospital, New York.—Dr. Henry D. Nicoll has been appointed Dr. Thomas's successor as Surgeon to the Woman's Hospital.

The Boylston Medical Prize of four hundred and fifty dollars has been awarded by Harvard University to Dr. George H. F. Nuttall, of San Francisco, for a dissertation entitled, *A Contribution to the Study of Immunity*.

Doctors and the New West Side.—If doctors' signs are any indication of disease, says the *New York Sun*, the new West Side must be one of the unhealthiest parts of the city. There is a doctor's sign on every large apartment building, and they average about one sign to every five or ten private houses. The real secret of their frequency is not that there is business in that part of the city for all the doctors, or for one-quarter of them, but that the recent rapid development of that section has led scores of young doctors to go there to grow up with the community in the hope of some day getting together practice enough to live. About one in a dozen of the earliest comers did really find a practice growing up around him, and a few of the West Side doctors therefore are getting rich fast, but for the rest they come, stay a few months, or as long as their capital lasts, waiting for the practice that never comes.

The Whitechapel Murderer and Physiology.—The Paranoiac Anti-Vivisectionist, Miss Frances Power Cobbe, has a theory that the Whitechapel murderer is "a physiologist delirious with cruelty."

Vaccinating Against Cholera.—Dr. Gamaleia has left Odessa for Paris, in order to explain his system of vaccination against Asiatic Cholera to the Académie des Sciences. In March he proposes to go to India, to test practically the efficacy of his method on cholera patients.

Laymen in Medical Positions.—The Chicago Medical Society has established a new test of medical ethics. At a meeting held recently the following resolutions were adopted by a two-thirds vote:

"*Resolved:* That this Society regards any physician who attempts in any manner to place a layman in a medical position as guilty of the most unprofessional and disgraceful conduct.

Resolved, further, That a committee of five be appointed to wait on the County Commissioners and demand that all county medical institutions be placed and kept under medical control.

"Furthermore, That it demand the same privileges for the Chicago Medical Society in the matter of the county hospital as are now granted to the Chicago Homœopathic Society."

The object of the resolutions, is, we believe, to secure competent medical management of the Cook County Medical Institutions.

Chicago seems to have an unfortunate time with her public medical institutions. Without possessing a single one which can be considered entirely creditable to a great city, there is a cloud of contentiousness hanging over those which she does support. The Chicago Home for Incurables is now in trouble, and the Medical Board has resigned.

To Limit Marriage.—A bill has been introduced into the Legislature of Kentucky which prohibits marriage with an idiot, lunatic, pauper, vagrant, tramp, gambler, felon or any person rendered physically helpless or unfit for the marriage relation, or any person with a violent temper, or who has, within one year, been a frequenter of any immoral house.

Trouble in the Garfield Hospital.—The Washington correspondent of the *Maryland Medical Journal*, writes: "It is not unlikely that some effort will be made to secure a reorganization of the Board of Directors of the Garfield Memorial Hospital, for of late many things have occurred, for which the present Board is entirely responsible, that cannot be pleasing to those by whose efforts the institution was founded, and who have control more or less over the Congressional purse-strings upon which it is dependent. It will probably be their wish to know why a reputable physician was summarily dismissed from the attending staff to make place for a surgeon of one of the divisions of the Canadian Pacific Railroad, who is an Irishman by birth and not a naturalized American citizen; why the nurses hitherto employed were ejected and Canadians substituted; why a resignation was virtually forced from the gentleman who had served the hospital faithfully as Assistant Resident Physician; why the applicants for the position of resident physician, who were graduates of local colleges, were passed over with so little consideration, and a Canadian, about whom the board practically knew nothing and had never seen, was chosen to fill this post."

The University Medical Magazine is the title of a new monthly, edited under the auspices of the alumni and faculty of medicine of the University of Pennsylvania.

The Fever at Jacksonville dies hard. On November 13, despite a frost, there were reported 30 new cases. The total number of cases now is 4,511, with 388 deaths.

The Empress Eugenie has given directions that her body be cremated after death.

M. V. M. A.—Emperors may die, dynasties may fall, presidential elections may come and go, the stars may drop out, the sun weaken its fires, Mr. Sullivan, of Boston, may be ill of alcoholic gastritis, the base-ball player may become an object of apathy and contumely, Professor Nichtweissetwass, of Germany, may patent a new antipyretic, or discover a new method of treating consumption; but all this is nothing to the recent meeting of the M. V. M. A. at St. Louis, or elsewhere, recently, as described and echoed by our esteemed contemporary the *Medical Weekly Review*.

"Vesuvius," says our enthusiastic contemporary, "Vesuvius never erupted more grandly, nor did Pompeii ever fall more gloriously than on the evening of Tuesday, the first day of the session, when their efforts were directed toward the particular pleasure of the M. V. M. A. members. The burning sentiment 'Science and Sociability United' was a pronounced and perfect announcement of an obvious fact, although the pyrotechnic artist who constructed the mechanism was a little off on his orthography when he made it read 'Sciance.'

Truly, what are the palsying restrictions of orthography when compared with the Pompeiean splendors of a M. V. M. A. banquet? What is still better, the eruption and the fall all took place before the hour of 8.30 P. M., until which blighting moment "All went merry as a marriage bell, and all too soon time rudely clipped the wings of eloquence and sped the parting guests," to a concert by Colonel Gilmore, of brass band and Coney Island fame, where, "the vibrations which wafted out upon the evening air the divine tones of Home, Sweet Home, completed the capture of the hearts of the visitors, and it was a rude awakening when the hour came for separation and the final good-byes."

Next to being Agamemnon or Achilles, it is most important to have a Homer to sing of the great deeds. The members of the M. V. M. A. as they rode home on the M. C. & St. P., on the B. & Q., and I. C. R. R., reading the admirable accounts of what had happened at St. Louis, must have felt that they were fortunate mortals, individually and corporately. Yet we hear almost nothing of all this in our esteemed and supposably enterprising Chicago exchanges. Thus does the gnawing tooth of jealousy excavate the vitals of the progressive journalism of the Lakes.

The Maritime Medical News is the title of a new medical journal which has just reached us. It is edited by five medical gentlemen, and published monthly at Halifax, Nova Scotia.

Society Reports.

NEW YORK NEUROLOGICAL ASSOCIATION.

Meeting held October 2, 1888.

PRESIDENT, DR. GEORGE W. JACOBY, IN THE CHAIR.

DR. B. SACHS presented three cases of

MUSCULAR DYSTROPHIES,

comprising the original part of his paper before the American Neurological Association in Washington. The author referred to the relation between pseudo-muscular hypertrophy and other forms of muscular dystrophies, particularly Erb's form. Erb had stated that the two were identical. Erb's juvenile form consisted in atrophy attacking the upper extremity, particularly the deltoids, the infraspinatus, and sometimes the latissimus, the lower extremity being intact. The question was whether pseudo-hypertrophy and Erb's atrophy were distinct or merging types.

CASE I. was twelve and one-half years of age. The child had suffered from severe fright at ten months. She had never walked well. She had diphtheria when four years of age, and after this her gait had been worse. When six and a-half years of age, increased size of the legs had been first noticed. The characteristic difficulty in getting up from the floor had been present. There was atrophy, commencing in the palmar interossei and affecting the arm and forearm. The thenar and hypothenar eminences had not been involved. There was hypertrophy of the whole lower extremity, but the hypertrophy of the legs had not kept pace with that of the thighs. It was apparent that atrophy of the legs would soon supervene. The atrophy of the hands had not been present two years ago. The case proved that in the atrophy associated with pseudo-hypertrophy it was not necessary that the shoulder should be first affected, as in Erb's form. For the interossei to be attacked first was rare, but only proved that any muscle could be affected by the disease, while Erb had stated that the hand was exempt to the last.

CASE II. was that of a boy ten years of age. There was no history of heredity and no constitutional taint. The patient was a newsboy. He had walked late and had been treated for rickets. He had never been able to run, and had been always easily fatigued. The hypertrophy in this case was most marked in the thighs. A peculiarity of the case was the fact that the boy could rise from the floor without climbing upon himself, as was customary in the disease and considered by Gowers a differential test. There was some atrophy of the serratus anticus of the right side. The upper extremities were not affected.

DR. BIRDSALL suggested that the face had a peculiar appearance.

DR. SACHS had not referred to this peculiar puffiness because, while suggestive, it was not sufficiently characteristic of the Landouzy-Dejerine type. It was possible that it might develop into this appearance.

CASE III. was that of a girl twelve years of age. She had walked at nine months. At the age of ten months she had fallen, and later had had something the matter with the knee. This was treated with the plaster splint in St. Petersburg, and recovered. The circumstance was mentioned because it had been denied that so young a child could be successfully treated with this instrument. At the age of three the child had measles, at four smallpox, at six scarlet fever, and at six and one half typhoid fever. The loss of power in the limbs was not preceded by fever or convulsions. Five months ago it was noticed that motion was impaired in the toes, there was a modified gait, fatigue, and difficulty in mounting the stairs. There was no pain. There had been at times a creeping sensation of the skin, and once fibrillar contractions had been noted. The atrophy affected the right leg, thigh, and gluteal region. The electrical reactions were normal. For four months the knee-jerk had been absent upon both sides, but now it was exaggerated upon the left side, while upon the right side it was still absent. The gait was that of poliomyelitis affecting the anterior group, while the history was one of progressive muscular atrophy of the peroneal form. The gradual onset, without convulsions or fever, and the progressive character of the affection, and the atrophy, which was not so profound, distinguished it from atrophies of spinal origin. On the other hand, however, the exaggerated knee-jerk suggested a substratum of spinal or neuro-spinal implication. The case was an anomalous one of a type seldom seen. The author inclined to a diagnosis of progressive muscular atrophy.

DR. BIRDSALL had been interested in the types shown, and was not inclined to question the doctor's diagnosis. The last case was, he thought, allied to the progressive muscular atrophy type rather than to that of an acute poliomyelitis; he thought, however, that there might be grades between the two, that there was no sharp line of demarcation between them. The former presented the characters of a degeneration while the latter was an acute inflammatory condition which might involve not only the gray matter but extend to the neighboring tracts. The speaker had a case in mind diagnosed acute inflammatory poliomyelitis. There was involvement of the muscles of the anterior and posterior aspects of the thigh, slight affection of the anterior tibial group, and exaggerated reflex, showing extension to the lateral collum. In the speaker's opinion the different varieties of atrophy represented grades rather than distinct pathological entities. The fact that the atrophy in one case had affected an arm, a leg, in one was hemiplegic and in another paraplegic, should not blind one to the possibility that the pathological processes might be the same. In the present stage of our histological knowledge he thought that we were not even able to separate cases into those of myopathic and myelopathic origin. The number of the cases was meagre and our methods of examination were not calculated to reveal minor degrees of atrophy. In the muscles, nerves, and cords it might be possible to have a gradual destruction and regeneration going on which would escape detection. The value of the electric reaction was equally open to doubt. If fibres degenerated one by one, it was probable that the reaction would remain normal until the number of atrophied fibres had attained a certain grade. The degeneration-reaction would be, in any case, interfered with by the normal reaction of the healthy fibres. The question was whether there was great uniformity in these various types or great diversity; he predicted the latter, the types running into each other.

DR. PUTNAM-JACOBI suggested that the gluteal muscles were unaffected in the second case presented. This accounted for the lack of the usual difficulty in getting up from the floor.

DR. SACHS was of the same opinion. He referred to the point because Dr. Gowers had mentioned the symptom as pathognomonic.

DR. DANA referred to a case of pseudo-hypertrophy in which the disease had advanced from the calves to the thighs, and thence to the shoulder-girdle. There was slight hypertrophy of the forearm, the part said to be unaffected in Erb's form.

The fundamental distinction between the symptoms of chronic anterior poliomyelitis and progressive muscular atrophy was the retrogressive or stationary character of the former and the progressive character of the latter.

It was difficult to criticise the diagnosis in Dr. Sachs' last case. He would prefer to postpone his decision, but would suggest that a careful examination of the urine be made for lead. A number of cases of anterior poliomyelitis in children had been recently ascribed to lead.

DR. GRAY would, upon *à priori* reasoning, decide the case as one of chronic anterior poliomyelitis, but that anterior-horn myelitis was, as had been suggested, retrogressive. Muscular atrophy could be, he thought, divided into that of spinal and peripheral origin; of the latter, however, we must distinguish between that arising in the muscles and that due to peripheral neuritis.

The results of treatment varied. There were cases which, with rest in bed, faradism, and gentle massage, improved, while other cases were unaffected by treatment. He thought that the former were of spinal while the latter were peripheral, either neural or muscular in origin.

Formerly the diagnosis of a central or peripheral origin was determined by the presence or absence of the reaction of degeneration. Now confusion surrounded this test also. The doctor inquired in regard to opinion upon this point. Was the degeneration-reaction present only where the muscles were degenerated?

Dr Sachs closed the discussion. He was pleased that Dr. Birdsall, who had not heard his paper in Washington, had been in substantial agreement with it. While there was diversity of types there was no anatomical distinction between pseudo-hypertrophy and atrophy. The primary and secondary affections were distinguished by their symptoms. The primary affection occurred early, there was absence of fibrillary contractions, and absence of the reaction of degeneration. This group included pseudo-hypertrophy, Erb's type, and that of Landouzy and Dejerine.

Dr. Gray begged to refer to a case recorded by Schultze which had been assumed to be primary, but in which there had been found changes in the cord.

Dr. Sachs explained that the change referred to was independent and unconnected with the muscular symptoms. It was in a part of the cord unconnected with the muscular tract. He suggested that in Dr. Dana's case the atrophy in the arm might have given rise to a fictitious appearance of hypertrophy in the forearm.

Dr. Dana added that the muscles had also the peculiar feel of pseudo-hypertrophy.

Dr. Sachs did not question the doctor's diagnosis. He believed that all present had agreed upon the desirability of getting rid of the present classification upon anatomical distribution of the hypertrophy or atrophy. He had retained the term peroneal form for convenience only.

Dr. M. D. Field followed, with a paper entitled

OTHÆMATOMA OR INSANE EAR.

The title referred to a shrunken, shrivelled condition, preceded by a period of active congestion during which the organ was swollen, hot, and very painful. Between the cartilage and the perichondrium there was effused a sero-sanguinolent fluid which might become purulent. This was absorbed, or rupture occurred, with healing and the deformity described. The deformity was not uncommon among the insane. It had been attributed to trophic change. The most general opinion had been that othæmatoma was characteristic only of chronic cases, and usually indicated an incurable condition.

The question of a traumatic origin had received some attention. It had been remarked that a Greek statue represented a boxer with this deformity. The author could not recall the reference. It had been said to result in boys from the violence of the game of foot-ball. It had also been observed among soldiers.

The author had had under his care the case of a professional pugilist who had presented the deformity in question. Upon directing his attention to it, the man had remarked that it had resulted from a blow upon the head, and that it was common in his profession—that he knew as many as a hundred men similarly injured. Arrangements were made with this man to be present at the meeting. He had been unable to come, but had sent substitutes. Several undersized, meek-looking professional men—pugilists—here appeared, all presenting the deformity. It should be added that only one had ever been in an asylum. This one had been in for delirium tremens. It was evident that the insane ear could proceed from traumatism; also, that it was more common than was commonly supposed.

Dr. Petersen felt indebted to Dr. Field for the opportunity of examining the cases. He had seen the condition frequently in the insane, and believed that it was always due to traumatism. It was more frequent among the insane, probably on account of the necessity for restraint, also because the insane were apt to injure themselves in many ways. He also believed that the changes in the walls of the vessels in insanity predisposed to the result. Retrograde metamorphosis of the cartilage and perichondrium, like that of senility, was common in general paresis and other varieties of chronic insanity.

Dr. Parsons exhibited a cast of othæmatoma in the recent state taken some years ago. He had always considered the condition a result of nerve-degeneration. The exhibition this evening had, however, demonstrated that it could result from traumatism alone.

Dr. Douglas had seen a considerable number of instances of the insane ear, and thought that it had been due to violence in every instance, either from the attendants, other patients, or the sufferer himself.

Dr. Ingram could corroborate this statement. The insane had the habit of rubbing the ears, which might account for some cases. He could add to Dr. Field's record that of a case of recovery after double hæmatoma during an active maniacal attack. With improvement of the mental condition there was improvement in the ear. Upon recovery there was diminution in the size of the ear, but no deformity.

Dr. Petersen added that the reference to the Greek statue had been by Fuerstner, Arch. f. Psych., III.

Dr. Field, in closing the discussion, referred to the case reported by Dr. Hunn; after the patient had been struck with a broom-stick the hæmatoma appeared upon the opposite ear. Dr. Hunn cited the case as an instance in which traumatism could not have been the direct cause.

Catalepsy in both Mother and Child.—Dr. Van Schoot reports a case of convulsive seizures of a peculiar kind in a woman in the seventh month of pregnancy. When he first saw her she was motionless, her face being cyanotic, but her temperature, respiration, and pulse normal. She was quite unconscious, and the slightly dilated pupils did not react to light. The arms were flexed at right angles, requiring some force to move the forearms. By means of chloroform all the contracted muscles relaxed, and some hours' sleep was obtained. Afterward she remembered nothing of the fit, but she stated that all movements of the fœtus seemed to have ceased, and no heart-sounds could be detected. These attacks were repeated frequently for a fortnight, the urine being quite normal all the time. Large doses of bromide were given without effect, but some amelioration was produced by sulphate of atropine. Latterly the attacks were associated with considerable movements of the abdominal muscles. Some temporary benefit was obtained by subcutaneous injections of pilocarpine. At the conclusion of a fortnight from the first attack labor came on, a female child being born alive, which, however died in a week's time, after repeated convulsions similar to those affecting the mother. The mother had no attack till the fifth day (the same day that the child's first attack occurred). After this there was only one more attack, two days later, complete recovery ultimately taking place. The author, referring to the diagnosis, is disposed to exclude eclampsia, because, although there were clonic contractions of the abdominal muscles, the main spasm—indeed, at first the only kind of spasm—was tonic. The entire absence of albuminuria, too, tends to exclude eclampsia. Again, epilepsy may be excluded, as after the tonic no clonic spasms occurred, and as the limbs remained fixed in a certain position for one or two hours. He therefore considers that the attacks were of a cataleptic nature, both in the mother and child.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE CLINICAL SOCIETY—A CASE OF INJURY TO THE ELBOW-JOINT INVOLVING THE ULNAR NERVE—PULMONARY GANGRENE TREATED BY INCISION AND DRAINAGE—A CASE OF EXTENSIVE ANCHYLOSIS OF THE SKELETON—MEDICAL SOCIETY OF LONDON—A CASE OF ABDOMINAL SECTION FOR INTESTINAL OBSTRUCTION—TREPHINING THE STERNUM—THE HARVEIAN ORATION—THE RELATIONS OF MICRO-ORGANISMS TO DISEASE—THE ARMY MEDICAL SCHOOL—THE COMING AMALGAMATION OF THE DUBLIN MEDICAL SCHOOLS—A SIMILAR SCHEME FOR LONDON—THE LESSENED MORTALITY OF ABDOMINAL SECTIONS AND THE CAUSES THEREOF—CASES OF RECOVERY FROM BRAIN INJURIES—A CONVENIENT METHOD OF OPERATING FOR AUDITORY EXOSTOSES—A NEW METHOD OF RAISING THE EPIGLOTTIS.

London, October 19, 1888.

At the first meeting of the Clinical Society, after a few introductory remarks from the President, Mr. Nunn read a case of injury to the elbow-joint involving the ulnar nerve. Dislocation forward of the radius had occurred, and when the patient was seen by Mr. Nunn (two months after the accident) there was loss of sensation in the ring and little fingers, and some indistinct thickening in the ulnar nerve above the elbow. Mr. Heath remarked that such cases were difficult both to diagnose and to treat. In doubtful cases the best treatment was to flex the elbow and lay the forearm obliquely across the chest, so that the hand rested on the opposite shoulder.

Dr. Pasteur then described a case of pulmonary gangrene which had been treated by incision and drainage. The patient was a boy, seven years of age, whose illness began insidiously but developed rapidly. On the tenth day of his illness he was admitted to the Northeastern Hospital for Children. He was then febrile, with coated tongue, quickened breathing, and gangrenous fetor of breath. His breath had become offensive the day before admission, on which day also he had coughed up a quantity of bright blood. There were signs of consolidation over the right upper lobe. During the next three weeks cavity-signs developed at the right apex. The rest of the right lung became pneumonic. The temperature ranged from 100° to 103° F. Three weeks after admission the pulmonary cavity was opened by an incision in the second right space, one inch from the sternum. A large quantity of gangrenous lung and putrid fluid was expelled from the wound. The cavity was found to extend to the sixth space, where a counter-opening was made, and flanged tubes inserted. Great improvement ensued, but was only temporary. Fetor of breath reappeared on the tenth day, and the patient sank rapidly three days later. At the necropsy a huge gangrenous cavity was found occupying the anterior part of the lung, and implicating all three lobes of it. It was lined for the most part with a thin layer of granulation-tissue. The necrotic process had invaded the pericardium and set up acute pericarditis. The œsophagus was adherent to the bronchus, and the two tubes communicated by means of a narrow sinus three-quarters of an inch in length. Dr. Pasteur remarked that the gangrene was undoubtedly due to the passage of some irritative material from the œsophagus to the lung along this sinus. The amount of repair which took place under unfavorable circumstances was encouraging, and an earlier operation might have saved the life of the patient. Mr. Godlee referred to a case of Dr. Poore's in which he had operated, but unsuccessfully as regarded saving the life of the patient. Mr. Nunn alluded to a case of abscess of the lung in which Mr. R. W. Parker had operated with a most successful result.

Dr. Alexander Morison then related a case of extensive anchylosis of the skeleton, with diaphragmatic breathing. The patient was a man, forty-four years of age, with a neurotic and rheumatic family history, and himself rheumatic. He had had gonorrhœa, which was followed by the anchylosis. The joints chiefly involved were both shoulders, both hips, all the ribs, and the vertebral column. Thoracic respiration was abolished, but its place was taken by exaggerated abdominal breathing. The expiratory capacity of the chest was much reduced, and the pectoral muscles atrophic. The patient had recently begun to deposit fat. Mr. Godlee referred to the case of a man with chronic knee trouble who had contracted gonorrhœa, since which all his joints had stiffened. Mr. Hutchinson said he thought there were cases of spondylitis deformans, without a suspicion of gonorrhœa, which were quite as bad as Dr. Morison's case. He believed that cases of gonorrhœal rheumatism only occurred when there was a very strong tendency to rheumatic gout. Dr. Barlow said he had seen four cases of general anchylosis, and only in one was the disease due to gonorrhœa. Dr. Angel Money said he had seen some cases in which the condition was the outcome of a peripheral neuritis. He had also seen a case in which there was a blue lead-line on the gums, and suggested that lead-poisoning, which was productive of gout and peripheral neuritis, might have something to do with these cases.

At the first meeting of the Medical Society of London the President (Sir William MacCormac) gave an introductory address, in which he dwelt at some length on the distinctions between ancient and modern surgery. Mr. Edmund Owen then narrated a case in which he had operated for acute intestinal obstruction. The patient, a woman, aged fifty, had long been in the habit of taking a purge every Saturday night, and one Sunday morning she was seized with violent abdominal pains. Vomiting ensued, and constantly occurred throughout Sunday and Monday. The abdomen became distended and tympanitic. Mr. Owen performed abdominal section and found (and tore through) an omental band constricting the small intestine. A few inches higher up the bowel was a permanent annular constriction, which had evidently been caused by the long-continued pressure of the same band. Mr. Owen suggested that this piece of bowel had become gradually accustomed to the pressure, but that probably the action of the purgative had caused displacement and subjected a fresh piece of bowel to the strangulation.

Mr. Ballance related the case of a woman in whom symptoms of suppuration in the anterior mediastinum manifested themselves. Examination with a probe revealed the presence of pus, and the sternum was trephined. It was then found that the suppuration was due to caries of the posterior surface of the sternum. The carious bone was removed, the cavity frequently washed out with sublimate solution, and the patient made a good recovery. Mr. Sheild said he had seen pyæmic abscesses perforate the sternum.

The annual Harveian oration at the College of Physicians was delivered on Thursday last by Dr. P. W. Latham, who took a somewhat novel departure. Previous orators have mostly confined themselves to a eulogy of Harvey's life and labors, and to describing, and pointing out the significance of the discoveries made by him. Dr. Latham remarked that these topics had been exhaustively discussed by his predecessors, and he therefore proposed to discuss some of the discoveries which had been made in modern times in matters connected with the circulation. After briefly referring to the discoveries made by Malpighi, Leeuwenhoek, Hales, Cowper, Haller, Lieberkühn, Prochaska, and others, he went on to consider the relations of micro-organisms to disease. It had been proved that certain diseases, as anthrax, relapsing fever, and tubercle, could be produced in healthy animals by inoculation with the bacilli characteristic of those disorders. When certain "non-pathogenic" bacilli, however, were introduced into the blood of the lower animals, even in large numbers, they were speedily destroyed by the living blood, or, when injected into the tissues, by the cellular elements of the latter. If the bacilli were not destroyed, but were such as were able to live in the blood or tissues of living animals, various chemical products were formed in connection with their growth, and among these were certain chemical poisons capable of destroying life. The chemical constitution of ptomaines was then discussed. Not only, however, had it been shown that certain poisons or ptomaïnes could be derived from dead putrefying animal substances, but it had also been shown by Gautier that certain bodies (leucomaines) having poisonous properties were formed within the living organism and independently of the action of bacteria. Dr. Latham suggested that these various substances (ptomaines and leucomaïnes) might be derived from the disintegration of albumen. He had, he said, in the Croonian Lectures for 1886, endeavored to show that there were grounds for regarding living albuminous compounds as made up of certain cyan-alcohols united to a benzine nucleus. He now proceeded to point out, by the aid of chemical equations, how ptomaïnes and leucomaïnes could be derived. As an illustration of the view advanced that in living animal organisms, various substances, such as extractives and alkaloids, were produced by slight departures from normal nutrition, and entirely independent of any bacterial action, Dr. Latham referred to the pyrexia which, even in healthy individuals, might follow excessive fatigue. Reverting to the consideration of the bacilli, Dr. Latham observed that it was only in particular conditions of a tissue, or at special times in its growth, that it furnished suitable soil for the growth of the bacilli. An example of this in the vegetable world was quoted from De Bary, and as an instance in the human subject, Dr. Latham remarked on the rarity with which ringworm of the scalp was seen in children over sixteen; some change had taken place in the tissue of the scalp which rendered it less suitable for the growth of the parasite. In phthisis the resisting power of the tissues to the bacilli was an important element, and in the prevention and treatment of consumptive mischief our aim must be not so much to fight against the bacilli as to strengthen the parts attacked. In concluding his oration, Dr. Latham said there was one important point to refer to in connection with these micro-organisms; could harmless organisms acquire (under any mode of cultivation) virulent properties enabling them to attack living animal matter? Pathologists and bacteriologists differed strongly on this point, but in the vegetable kingdom instances were not rare of cells possessing poisonous properties at one time and not at another.

It is always well to hear both sides of a question. I referred last week to the proposed obliteration of the Army Medical School at Netley. The general opinion as to this scheme is that it would be a misfortune should it be carried into effect. I have, however, just heard the opposite view very forcibly put forward by a very distinguished and well-known retired army medical officer. To his mind it would be an unqualified benefit if the Netley course were to be abolished. The teaching there he regards as of doubtful value, being largely theoretical, and not calculated to prepare the young army doctor for the practical duties of his daily life. While there, also, the future army medical officer is likely to acquire absurd notions about rank and precedence, and to imagine that the medical staff is a separate corps like the engineers, all of which ideas may hereafter cause him trouble. Such were some of the aspects of the question as presented to me by my informant. He further deplored the abolition of the "regimental system," under which one surgeon was attached to a regiment, three junior medical officers acting under his directions being styled "assistant surgeons." The latter acquired practical experience of great value while acting as juniors, and the title of "surgeon" was then much more valuable than now, being only conferred after several years service. In lamenting the decay of the regimental system, I know that my friend has many sympathizers. It was certainly of incalculable advantage to the soldier himself, for when it was in vogue he was attended, when sick and wounded, by a medical officer who knew him personally, and was intimately acquainted with his medical history.

LONDON, October 27, 1888.

THE approaching amalgamation of the medical schools in Dublin is exciting some comments in the metropolis. There are not a few who say that a similar step should be taken here. Out of our eleven schools of medicine, only about half can be said to be completely equipped with teaching appliances, the paucity of students and of funds in the remainder preventing them from competing with their rivals on equal terms. This could be remedied if amalgamation of some of the smaller schools were to take place. It is no answer to those who advocate this to point out the (in many cases) superior advantages of the smaller schools for the purposes of clinical study. These would still remain, for no one proposes to close any of the London hospitals, or to disuse for clinical instruction any of them thus used at present. A union of schools, or of some of them, would, however, be of unquestioned value as regards the more strictly scientific parts of medical study. One difficulty at the outset would, undoubtedly, be how to deal with the superfluous teachers. For example, there are at present eleven lecturers on anatomy in the London schools. In Dublin the difficulty is being met by granting an allowance to some of the professors equal to four years' fees and allowing them to retire. Some such plan would doubtless be adopted here, if the scheme were to be carried into practical operation in any form.

At the last meeting of the Royal Medical and Chirurgical Society Mr. W. A. Meredith read a paper on "Some Points Affecting the Mortality of Abdominal Sections." Tables of cases were given—chiefly in reference to ovarian disease—from which it was shown that the mortality of such operations has greatly diminished of late years. Mr. Meredith attributed this chiefly to a diminution in the number of deaths from septicæmia, a diminution largely due (in his opinion) to the adoption of the intra-abdominal treatment of the pedicle, the general abandonment of the practice of tapping, the better systems of drainage, and the free washing out of the peritoneum. Mr. Doran congratulated Mr. Meredith on his tables. As to antiseptics, they were, he said, without doubt useful, for, whatever might be their other properties, their careful use was a kind of drill for nurses and surgeons. Every beginner should use them most carefully, though it might be that his most brilliant results would come later, when he had given them up. A hospital nail-brush in common use was dangerous, for it conveyed more infection than it swept away. The flushing-out of the peritoneum was a very important matter, combined with drainage properly understood. Mr. Knowsley Thornton said he disliked the use of the drainage-tube much less than he had done, but could not consider it as safe as Mr. Meredith did. He always washed out the peritoneum now in cases where it contained any septic material, for he thought that flushing the peritoneum often broke up septic material into tiny particles which were unable to withstand the healing power of the peritoneum. He was of opinion that all should begin with antiseptic methods. It was a most important training which made careful forethought absolutely necessary. The advantages of the nail-brush to the surgeon were very clear to him, and anyone who felt as Mr. Doran did should always have a private brush in his waistcoat pocket. Mr. Meredith, in reply, observed that the use of the drainage-tube seemed to him to be of great advantage, and in cases of antiseptic treatment he did not find it desirable to change it more than once in every twelve hours. The treatment of cases occurring about the menopause was important, for women were then passing through a critical time, when kidney trouble often developed, which would impede absorption of peritoneal fluid. After that period drainage was not so often wanted.

At the Medical Society of London, on Monday last, Dr Fletcher Beach read notes of a case in which a lacerated wound of the brain (an inch in depth) in the occipital region was caused by a window pole. There was fever and some delirium. Four weeks after the accident a cerebral abscess broke through the wound. Complete recovery, however, ensued. The treatment, apart from the local use of antiseptics, was confined to tincture of opium in five-minim doses given at first, and afterward draughts composed of ten grains of chloral and fifteen grains of bromide of sodium, to subdue the restlessness and relieve the pain in the head. Mr. Knowsley Thornton mentioned the case of a boy, aged seven, who was accidentally struck on the head with a manure fork, one of the prongs of which, laden with filth, passed through his skull. The wound was dressed with cold compresses and the patient made a perfect recovery. Mr. Thornton suggested that children bore these injuries better than adults. Dr. Symes Thompson concurred in this remark, and referred to the case of a boy who was trephined for suspected abscess of the brain. The abscess was only reached after the trocar had been plunged three times, for a depth of two inches, into the brain substance. Nevertheless a good recovery ensued. Dr. Beevor mentioned the case of a boy who sustained a compound fracture of the frontal bone but recovered perfectly, although a good deal of dirt and straw was forced into the wound.

Mr. Marmaduke Sheild then narrated a case of exostosis of the auditory canal. The growth nearly blocked the canal, and the symptoms were urgent. It was removed by the following operation: The auricle was divided posteriorly where the pinna joins the cranium, the cartilage of the canal was exposed, divided, and displaced from the bone. The chisel was applied to the bone at the base of the exostosis, and the latter then easily removed. The auricle was then replaced, sutured with catgut, and soon united in its normal position. All pain disappeared on the following day, and the hearing was satisfactorily restored. The adaptability of the operation to cases of exostosis and foreign bodies was pointed out. Where drilling was necessary, the procedure adopted in this case would enable the operator to obtain complete command over the growth, which was brought directly under eye and touch, enabling the surgeon to use a short drillhead, by which greater power could be exerted and the risk of slipping obviated.

Dr. Benjamin Howard then read a paper on a new method of raising the epiglottis. He said that when the epiglottis fell back over the laryngeal aperture, just as apnœa deepened into unconsciousness, traction on the tongue was altogether without any effect in raising the epiglottis. On the other hand, as he showed by the aid of diagrams, extension of the neck and raising the chin produced direct traction on that organ, and thus facilitated a return of respiration. He dwelt on the importance of recognizing the fact in chloroform narcosis and other forms of impending death from apnœa, and recommended in such cases that the head of the patient should be allowed to hang over the edge of the table, forcible extension being applied if necessary.

OUR PARIS LETTER.

(From our Own Correspondent.)

THE INCREASE OF RABIES IN PARIS—WHOLESALE DOG SLAUGHTER—A CASE OF CEPHALIC TETANUS—CORROSIVE SUBLIMATE AS A PROMOTER OF ADHESIVE INFLAMMATION IN RADICAL CURE OF HYDROCELE—LACTIC ACID IN THE DIARRHŒA OF NURSLINGS.

PARIS, November 2, 1888.

WHEN, a short time ago, M. Pasteur declared before a meeting of the Council of Hygiene of Paris that human rabies was on the increase in this city, and that in one day, viz., on the 19th of June, 16 persons bitten by rabid dogs (11 of whom were of Paris) presented themselves at his laboratory to undergo the anti-rabic treatment, the Prefect of Police issued orders to the effect that all stray dogs, whether with or without a collar, should be seized and taken to the pound, where they were at once destroyed. The Parisians, of course, soon protested against the summary manner in which their canine companions were disposed of, for since the publication of the police order about one hundred dogs per day were captured and killed. In consequence of the protestations of the owners of dogs the orders of the Prefect of Police have been somewhat relaxed, and it has been observed that rabies is not on the increase. All dogs unaccompanied are taken to the pound. Those wearing a collar with a brass plate on it, indicating the address of the owner, are kept for three days, at the end of which time, if they are not claimed, they with the others are destroyed without delay. Dogs that are known to have bitten, however, whether they be provided with a collar or not, are preserved in separate cages until they have been examined by a veterinary surgeon, with the view that if the animal is rabid the necessary measures be taken with the persons that may have been bitten. Immediately after their arrival at the pound the dogs that are to be destroyed are put into a cage with bars. As soon as this cage is filled (the number it contains being about thirty) it is wheeled into a metallic reservoir of a capacity of two or three cubic metres. The reservoir is hermetically closed. By the aid of a tap placed in the centre, lighting or coal gas is introduced. One side of the reservoir is covered with glass, through which it may be seen when all the dogs are entirely asphyxiated. The time necessary for this operation does not exceed three minutes. This done another tap, placed in the upper part of the reservoir, is opened, which permits the escape of the gas by a special chimney. The cage is then wheeled out of the reservoir, and the corpses of the dogs are taken out and are sold to a knacker for thirty centimes each. In looking through the glazed opening mentioned above, it is observed that the dogs fall almost immediately asphyxiated, without manifesting any sign of suffering. I may note that a certain number of dogs are made over alive to the faculty of medicine for the purposes of vivisection.

At a recent meeting of the Societé de Chirurgie Dr. Terrillon read a note for Dr. Charvot, on the case of a patient suffering from a contused wound in the right molar region, caused by a kick from a horse, producing what the author termed a "cephalic tetanus." The following is a summary of the case: Contused wound of the right molar region, right facial paralysis on the eighth day, trismus on the fifteenth day, accompanied with convulsive attacks of the face; then death suddenly followed four days after the onset of the accident. The temperature of the body remained low to the moment of death. Dr. Terrillon, who had to report on the note, remarked that this case was analogous to that which he had communicated to the Society in 1887, but in which death took place on the nineteenth day. Dr. Charvot, considering that the pain in the molar region was aggravated by pressure, divided the suborbital nerve without result. In concluding the reading of the note, Dr. Terrillon made the following extraordinary remark: "Here, also, is found confirmed the theory of the equine origin of tetanus defended by M. Verneuil," but what the horse had to do with the production of tetanus I am not able to understand. *Apropos* of this communication Dr. Reclus stated that he had just observed a case of tetanus at the hospital. Death took place in a ward where there had already been two cases of tetanus. As tetanus developed itself on the seventh day after the healing of the wound in all three cases, he concludes that the period of incubation of tetanus appears to be seven days. The first case was that of a female patient, who died in twenty-six hours. The symptoms consisted of trismus and pharyngeal symptoms, the latter constituting what has been termed hydrophobic tetanus, which Dr. Tillaux considers a just expression, as patients so affected resemble those that are suffering from rabies. It is also used in contradistinction to cephalic tetanus, which, according to Dr. Terrillon, is that which succeeds traumatisms in the zone of the trifacial nerves. Facial paralysis is one of the first and most important symptoms. It may kill without being generalized.

Struck with the fact that corrosive sublimate easily determines adhesive inflammation, Professor Richet has had recourse to it at the Hôtel Dieu for some years in the treatment of hydrocele. It is employed in the same manner as the tincture of iodine. The hydrocele emptied, a certain quantity of the liquor of Van Swieten is injected into the vaginal sac without distending it. The solution should be previously raised to about the temperature of the body, and this renders the injection painless. After three or four minutes the solution is allowed to run out. On the next day a moderate reaction takes place, but less intense than with the tincture of iodine. About the third or fourth day a thick plastic liquid is perceived by palpation, the vaginal sac, then ulteriorly the scrotum, diminish in volume and the patient is cured, having suffered less during and after the operation than if he had been treated with the tincture of iodine. Professor Richet has obtained good results by treating cold abscesses in the same way.

Experimenting with lactic acid, lauded by Professor Hayem for the diarrhœa of nurslings and against the diarrhœa of adults, Drs. Sézary and Aune, of Algiers, have recognized that this medicament succeeds perfectly in the diarrhœa of tuberculous subjects. It may be noted that lactic acid had already given good results in the treatment of local tuberculosis, and particularly in laryngeal tuberculosis. The lactic acid is administered at from two to six or eight grammes in a mixture of one hundred and twenty grammes per day, and by spoonfuls in the twenty-four hours. At this dose the patients often complain of the sensation of the teeth being set on edge, of gastric troubles which may be made to disappear by adding one gramme of chlorodyne to the mixture. From the second day the stools diminish in frequency, and become normal about the fourth day.

Dr. Ferran, so celebrated for his anti-choleraic inoculations, persists in forwarding his claim to the Academy of Sciences for the Bréant prize of one hundred thousand francs for the cure of cholera, against that of Dr. Gamaleia, of Russia, whom he accuses of having simply counterfeited his experiments.

HAS THE MORTALITY IN PNEUMONIA INCREASED?

To the Editor of The Medical Record.

Sir: The article by Dr. Gouverneur Smith, in your issue of October 20th, on the increase in the mortality from pneumonia, interested me greatly, as, stimulated by Dr. Hartshorne's paper, I have recently looked into the subject.

In the November number of the *University Medical Magazine* I discuss certain aspects of the problem, and present figures from three representative hospitals—the Montreal General in the North; the Pennsylvania Hospital in the Middle States; and the New Orleans Charité in the South—to show that there has not been any striking increase in the death-rate. In fact, at New Orleans, the percentage for the decade from 1830 to 1840 is the highest of the series, while at the Pennsylvania Hospital the record for the three years 1848–50—37.9 per cent.—was not exceeded, except in the triennial period of 1875–77, when the mortality rose to 39.2 per cent.

It is natural that the hospital records of our large cities should show an increasing death-rate in all acute diseases, for of late the pauper element has increased relatively, and probably the number of individuals admitted to hospital in a debilitated condition is much greater now than at any former period.

We need the accurate records of private practice, and, were they available for the past half-century, I believe the mortality under our more rational treatment would show the same striking reduction as is illustrated in the well-known figures which Bennett gives as the result of a change in methods at the Edinburgh Infirmary. I know of but one tolerably extensive series of this kind—that of Dr. Palmer Howard, of Montreal, who treated one hundred and seventy cases, with a mortality of only six and a fraction per cent. We should get at the truth of this matter, and, before accepting the statement of Dr. Hartshorne or acquiescing in the suggestion of Dr. Smith that a change in the method of treatment has been followed by an increase in the mortality, let us be certain of our figures. So far as I can ascertain, the evidence does not point to any specially augmented death-rate.

Pneumonia remains now, as then, the most serious acute disease with which physicians have to deal; serious, because it attacks the old, the feeble, and the drunkard—persons who are not in a condition to withstand the sudden, sharp onset of the malady. But pneumonia is now, as it was formerly, a comparatively safe affection in healthy adults, easily managed, and with a low death-rate. Half a century ago a certain number of patients in the former class were hurried to the grave by heroic treatment. Now and again, to-day, we lose a member of the latter group by failing to resort to the active measures which so often proved harmful in the hands of our predecessors. I have the honor to be, dear sir,

Yours truly, William Osler, M.D.

Philadelphia, Pa.

PURE AIR IN PNEUMONIA.

To the Editor of The Medical Record.

Sir: It is with great pleasure that I have read the article entitled "Pneumonia," and your editorial comments on the same, in the issue of October 20th. The subject is one to which attention has not been sufficiently called, yet I venture to say that a little more consideration for the ventilation of the sick-room (even, if necessary, taking the risk of the "eastern draughts of air that are arrows of death") will result in a reduction of the average mortality from this disease that will be as gratifying as it would doubtless prove surprising to many a clinician. New York is not alone in the higher mortality from pneumonia; our Cincinnati Hospital shows an annual death-rate of not less than thirty-five per cent., frequently more. The value of the "fresh-air treatment," for so we may justly term it, was particularly impressed upon me by a case observed in the wards of the London Hospital, under the care of that genial physician, Dr. H. J. Sutton, some eight years ago. The patient was a young woman, aged twenty-three, of the lowest social status, addicted to alcoholic excesses, a prostitute, who was admitted to the house during the latter part of January, with a lobar pneumonia of the right upper lobe. In the course of the next four days the whole of the right lung and the apex of the left lung became involved in the process. The general aspect of the case, the extent of the inflammatory process, and the familiar severity of the disease in this and other northern cities, involuntarily led to the framing of an unfavorable prognosis. Yet, despite the fact that the pneumonia did not terminate in resolution, that a large pulmonary abscess formed in the right upper lobe, that patient was walking about in the open air in the early part of April, in better health than she had enjoyed a long time before. The one thing that has kept the case so clearly before me was the singular line of treatment pursued. On the second day of her stay in the house after careful examination by Dr. Sutton, he ordered the window alongside her bed to be opened for five minutes every hour (this in a London atmosphere in January), to have the chest, arms, and face sponged every hour, and in addition free stimulation with sherry, whiskey, and carbonate of ammonia, together with Dover's powder, if there should be much pain. This practice seemed almost heretical to me; to open the window directly alongside of the bed of a patient suffering from pneumonia, in the coldest air of winter, seemed like wantonly hastening the fatal issue; yet the result proved the wisdom of the physician's directions.

Twice since then have I resorted to this plan of treatment myself. Both cases occurred in children, and both were desperate cases. One occurred in the latter part of December, the other in March. In both of these cases the bed was moved just alongside of the window, the sash was raised at least six inches, and this procedure was followed until the physical signs indicated the occurrence of resolution. Both of these children are now alive, strong, and hearty; and, though the *post hoc* does not always prove the *propter hoc*, I feel very sure that the fresh air had more to answer for the recovery than any other feature of the treatment.

Let our brethren not dread the fresh air in pneumonia. If it is impossible for the fever-stricken patient to catch cold, what is there to fear? The contact of the cold air upon the surface will lead to deeper inspiration; the colder air will find its way more readily into the deeper alveoli by mere displacement, and, according to the well-known laws of density, the cooler the air the larger the actual amount of life-bringing oxygen it contains. I hope that fresh air will be considered as the prime factor in the treatment, never, of course, to the total disregard of cardiac stimulants; and I am sure if this plan is more universally adopted, one of the most dreaded affections of our northern latitudes will lose many of its terrors.

Very respectfully yours,
Joseph Eichberg, M.D.

Cincinnati, O.

THE COUNTY SOCIETY AND THE PUBLIC WATER-SUPPLY.

(To the Editor of the Medical Record.

Sir: It is my belief that The Medical Record voices the sentiment of a large majority of the physicians of this city when it disapproves of the action of the County Medical Society in indorsing a private scheme for supplying the city with water. When Mr. Bartlett was invited to read his paper at the meeting in September not a member of the Society, unless by private understanding, knew that resolutions were to be presented indorsing his scheme. While there was a fair attendance on the meeting, and those present had listened with interest to the lucid description of our water-supply, both present and prospective, yet, when the resolutions indorsing Mr. Bartlett's scheme were offered for adoption, it seemed evident that but few of the members present understood them to mean more than an expression of thanks to the author for his trouble in preparing a paper for their instruction, and to voice the opinion that it would be better for the sanitary condition of the city to have as plentiful and pure a water-supply as is possible, and to warn against the present insufficiency. Some of those who spoke in favor of adopting the resolutions stated that such was their interpretation of them, and no one supporting the resolutions tried to disabuse them of that view.

It seems evident, therefore, that the action of the Society at that meeting not only failed to voice the sentiment of the great body of the profession belonging to the County Society as to supplying New York City with water by a private corporation, but that it also failed on that point to voice the sentiment of the limited number then present.

When at the next meeting in October Dr. Washburn offered resolutions rescinding those passed in September, there had been no previous notice given of his intention to do so; it was late, and the majority of those in attendance had left, and the handful remaining probably felt little inclination to open a discussion which might be continued by some hot heads far into the night. Consequently the resolutions, by a majority of one or two votes, were laid on the table.

I fully agree with The Medical Record that it will react to the injury of the County Society and of the entire profession for the Society to leave itself on record as in favor of supplying this city with water by some private scheme; but if its action in this matter is to be reconsidered I hope due notice will be given to all members, and that no one will be excluded from voting because he has not paid his dues. To exclude such from voting on such an occasion would not be the way to elicit the views of the profession of this city, particularly not of a large part whose sympathies, by reason of like surroundings, are more closely linked with those of the common people. Incidentally, I might suggest that the by-law permitting only those who have paid their dues to vote might well be suspended when it comes to assessing dues for another year. It seems rather unfair, when hard times have caused many members to fall, temporarily at least, in arrears of dues, to permit only those whom the hard times appear to have affected least to fix the dues which all alike must pay or be considered not in good standing in the Society.

At any rate, the Society can hardly expect to flourish if the comparatively few who may happen to be at a meeting are allowed to pass resolutions without previous notice, indorsing schemes like that which would give to a private corporation the power to say whether a million people shall have more or less water, of purer or less pure quality, and pay thus much or more per gallon. It may be, and I think doubtless is, well for physicians to take part in politics and the conduct of public affairs, but let them act as individuals, and never as a body except as it relates strictly to medical and sanitary interests.

If the action of the Society at its meeting in September is to be reconsidered, I trust notice of the fact will be printed on all cards of invitation. Sincerely yours,

A Member of the County Society.

New York, November 5, 1888.

DIPHTHERIA.

To the Editor of The Medical Record.

Sir: In reading Dr. Hope's article upon the use of peroxide of hydrogen in diphtheria, I was struck with his just criticism upon the vague way we talk about diphtheria being a follicular tonsillitis, and *vice versa*. I have attended many hundred cases of diphtheria—in all, including cases I have seen with my father and cases given over to my assistant, about four hundred. I was constantly puzzled, and still am puzzled, by the following cases: I am called to see a child with diphtheria; I examine the throat; I find several large ulcers upon the tonsils or upon the soft palate, or a nasal diphtheria with a high fever, glandular enlargement, albumen in urine, etc. I am about to isolate the child, when I am told that the other children, one or more, perhaps, have had sore throat and fever, and that they are now well. I examine the other children and sometimes find what looks to be a follicular tonsillitis almost gone. Again, I am called to see a child with a sore throat. I diagnose follicular tonsillitis. It is recovering, when another child is taken ill, and now I have a severe diphtheria; and the child almost dies, or even does die, with a most terrible diphtheria.

What are we to think? Is every case of follicular tonsillitis a diphtheria? My father has often told me, when he first came to New York, in 1846, and was studying medicine, that diphtheria was unknown. Croup there was, and tonsillitis, but no diphtheria. From this we must conclude that there is a special germ in diphtheria which has arisen from conditions in the atmosphere acting upon a diseased surface which we will call a tonsillitis, and is continued as a special poisonous germ. Or certain corditions of modern sewerage produce a gas or germ which, when powerful enough, will, with or without a tonsillitis, produce a disease known as diphtheria. I am inclined now to consider diphtheria a local disease. I consider that croup and diphtheria are not the same disease, and I think the reason why true croup almost always runs into a diphtheria is, that the germs which produce diphtheria are almost continuously found in the atmospherical condition in cities. Children are especially subject to diphtheria, and that is why we all dread a simple laryngitis, or a simple follicular tonsillitis in a child. I do not believe the subject of diphtheria has received sufficient scientific study. The literature upon the subject is vast but bulky, and as vague as voluminous.

There is no special method of curing diphtheria. It is a self-limited disease. Children get well without treatment. Children die with the best of treatment. Local treatment, if thorough, as the actual cautery, should, in my opinion, do well; but local treatment which merely irritates does harm. I now, except in adults, use no local treatment save the local treatment caused by the tincture of iron and quinine passing over the fauces. I simply help nature to resist the disease and, if you will, disinfect the ulcers and harden the surrounding tissues, until the fury of the disease is over and the child can resist the poison more effectually. I use mercury, but must confess that turpentine pleases me more. I have given mercury as thorough a trial as could be, and lost cases, and I have given nothing but brandy and saved others. I would, of course, insist upon cleanliness. Douche the nostrils thoroughly with a good disinfectant. Do not meddle much with the throat. Support the system with quinine, iron, and whiskey. In croup, calomel and turpentine do best in my hands. Steaming is good sometimes, but must be watched. A last resort is O'Dwyer's tube, or tracheotomy. I think we will have less now of the latter operation. The tubes have done away with tracheotomy.

Most truly yours,
MARTIN BURKE, M.D.

147 LEXINGTON AVENUE.

MISTAKEN DIAGNOSIS, PERHAPS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In THE MEDICAL RECORD of October 6th is given a detailed account of what purports to be a case of "Pneumonia with Delayed Resolution—Abscess Opening Externally—Recovery." With becoming respect, the question is raised as to whether the trouble described was in reality pneumonia. From the history given, the writer must be excused for coming to a different conclusion. Indeed, the case, as outlined by Dr. Benjamin Edson, has all the ear-marks strongly and sharply defined, it would seem, of suppurative pleuritis. Having no disposition to be hypercritical, and fully recognizing the fact that none of us are infallible, and consequently are not free from mistakes in diagnosis, even where much care has been exercised, the task of calling in question the correctness of a brother-physician's opinion is not especially pleasant and is assumed with reluctance; yet in the interest of medical science, and for the benefit of that brother, as well as others who may have read the article, it is thought to be the right thing to not let it go unchallenged. The case is suggestive, and of much interest, not only on account of error in diagnosis, perhaps, but because it shows up in a strong light the wonderful restorative processes of nature, and gives us better defined and more restricted notions of therapeutical aid. The lesson revealed, that the "vis medicatrix naturæ" is all-powerful and mighty to save in the battle with disease is a most important one, and should never be overlooked nor underestimated in efforts at treatment. The treatment in this case for the first five weeks was not only of no benefit, but must surely have been more or less harmful according to history of treatment. Evidently the first physician in charge did not know what was the matter, failed to locate the disease, and made severe applications where they should not have been made—over the left lung. According to admissions, the second physician in charge did but little to aid nature in the work of restoration. The patient is said to have "*ate* her way through." If the supposition be true that it was a case of suppurative pleuritis instead of pneumonia, then in that condition timely assistance, it must be admitted, would have been a great help to nature in such a trying ordeal. Possibly if fluid absorption in the early stage had been promoted by hydragogue, catharsis, diuretics, blisters, and restricted drink, or, failing in that, the fluid had been drawn off by aspiration or otherwise, resolution would have taken place without purulent action, thus preventing life from being placed in such great jeopardy. But even should purulence have characterized the fluid from the beginning, very great advantage in all probability would have resulted from its early withdrawal through surgical help. The powers of life would not have been so nearly exhausted, deformity not so great, and the danger of plastic exudations, binding the lung down, and preventing proper expansion after the fluid had been evacuated, would be lessened in a marked degree. It is hardly worth while to go into a critical analysis of the symptoms in this case, to show that it was suppurative pleuritis. If anyone interested will examine Flint's "Practice," and various surgical works on the question, after reading the history of the case, no doubt he will be well satisfied that it was plainly and unmistakably marked pleuritis of the empyemic order. Instead of an abscess forming, as mentioned, it was simply spontaneous perforation of the chest-walls to give vent to purulent pleuritic effusion, which always finally takes place in that way unless previously withdrawn through surgical interference, provided life should hold out so long. The contraction of the thoracic walls and deformity of the spine following evacuations clearly indicate the previous state of things. Besides, the character of the sputa, and the immediate subsidence of all bronchial and lung-tissue irritation, plainly tell us that parenchymatous inflammation could not have been the trouble. It is not improbable that in this case there was also some acute trouble of the kidneys. The consolidation spoken of was not lung hepatization; for the dulness doubtless resulted from pleuritic accumulation. The treatment to "allay irritative cough, stimulate the appetite, and sustain the strength" was quite in the right direction; but to do this and neglect the far more important consideration of evacuating the purulent fluid reminds one of "stopping the spigot and opening the bung." The diet of "steak, potatoes, bread and butter, clam-fritters, mince-pie, bananas, and oranges; used, in fact, without restraint to the quantity of double that required by a daily laborer," seems to be remarkable for its grossness and liberal supply. True, the child stood up to it, as she did to other things; being another manifestation of how wonderfully tenacious some persons are of life. The conviction cannot be resisted, however, that had the diet been more restricted and better suited for digestion under the circumstances, the child would, to say the least, have progressed equally well and perhaps better. Even if only a short time before natural evacuation took place the purulent fluid had been drawn off more gradually by aspiration or trocar, cannula, and suction, the resultant depression and general distress would have been much less marked, because time would have been given for the parts to adjust themselves to their new relations. While this case seems to have done reasonably well after evacuation, it has been settled beyond question that similar cases generally would be greatly benefited by washing out the pleural cavity at least once a day with weak solution of carbolic acid or other disinfectant tempered to that of the body. A study of this case forcibly impresses one of the need of a close acquaintance with the various processes of nature in removing disease and establishing health; and more especially does it impress the great importance of giving closer attention to the study of diagnosis. Physical diagnosis, in particular, should receive a larger share of consideration in student and college life, for most of us at some time in after-life feel but too surely the effect of this early neglect. No part of college and chemical study can be more profitably spent than in making oneself thoroughly familiar with physical diagnosis in all its aspects; and if college instruction would more strongly stamp this thought on the student mind, requiring at the same time a more thorough training and perfect knowledge in this behalf, it would confer an everlasting and untold blessing on the medical profession, and many sufferers from disease.

B. F. Hart, M.D.

Brownsville, Mo.

MATERNAL IMPRESSIONS.

To the Editor of The Medical Record.

Sir: A clinical note in No. 16, October 20th, of The Medical Record, page 479, on "Supernumerary Nipple" contains this statement: "The interesting point in the case centres in the possibility of the malformation being due to a so-called maternal impression." I would not trouble you with this reference if I did not constantly see similar expressions in medical journals of standing, like the Record, *Medical News*, *Journal*, etc., until the repetition of such nonsense becomes extremely wearisome. There is not a scientific physician on the face of the earth, who has any respect for his own reputation, who would accept a diagnosis of any obscure disease upon the evidence presented in this case, even where the disease named was well known to him. In this case the doctor never knew the mother of the patient, takes the statement of a woman on a matter said to have occurred seven months before the witness was born, to account for what he calls a malformation, when said malformation is one of the simple processes of nature quite common in the human species, both male and female, and a condition present in the great majority of mammalia of the lower orders. Again the said fright, the evidence of which would not be accepted in the commonest kind of a police-court, or even by a backwoods justice of the peace, was simply the scratch of a kitten, and the party frightened, having no *impression* of a nipple on her mind, nor anything else of that nature. Besides, the fact of the fright or the malformation, as is usually the case, was only brought to mind years afterward, and in this case the evidence given to the doctor came from a person who did not even pretend to know anything about the matter in any way whatever. It is a matter of some astonishment to every thinking man how certain superstitions of the past cling to the people, and especially to the uneducated, even where there seems to be some rational explanation for these superstitions. But when educated physicians, who are supposed to be the most critical observers, who accept nothing except that which has been demonstrated by the cold logic of science, who are forced daily to glean the truth from the multitude of falsehoods laid before them, who hold the lives of people in their hands and the saving of these lives may depend upon their faithfulness to demonstrated science—I say, it is still stranger that minds educated in such a school of experience should continue to be muddled by this baseless, nonsensical superstition, handed down by word of mouth from the ages of the past without the first principle of scientific reason ever having been produced to support it. Every writer of repute on teratology for a hundred years has utterly scouted at the idea, and no embryologist of to-day will even give the subject a passing notice. And since the experiments of Erciloni upon the placenta showing that the fœtus *in utero* is perfectly independent of the mother so far as nerve and vascular supply is concerned, but is joined wholly as a matter of nutrition just as it is while nursing, the repetition of this nonsense is calculated to make the searcher after truth extremely weary, to put it in the mildest form possible.

E. P. Murdock, M.D.

Chicago, Ill.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from November 4, 1888, *to November* 10, 1888.

Baily, Joseph C., Lieutenant-Colonel and Assistant Medical Purveyor. By direction of the Secretary of War will transfer at once the public funds for which he is now responsible to Captain Henry Johnson, medical storekeeper, who will assume temporary charge of the Medical Purveying Depot in New York City, retaining charge thereof until relieved in person by Lieutenant-Colonel E. P. Vollum, surgeon, under his assignment as Acting Assistant Medical Purveyor, to whom Captain Johnson will then transfer the public funds. Par. 1, S. O. 257, A. G. O., Washington, D. C., November 3, 1888.

McElderry, Henry, Major and Surgeon. By direction of the Secretary of War leave of absence for two months, to take effect on the completion of his present duties, is granted. Par. 3, S. O. 256, A. G. O., Washington, D. C., November 2, 1888.

Ewen, Clarence, Captain and Assistant Surgeon, is relieved from duty at Fort Sidney, Neb., to take effect on the expiration of his present leave of absence, and will report in person to the commanding officer, Madison Barracks, New York, for duty at that post. Par. 2, S. O. 258, A. G. O., Washington, November 5, 1888.

Appel, Daniel M., Captain and Assistant Surgeon, is relieved from duty at Fort Davis, Tex., and will report in person to the commanding officer, Fort Sill, Ind. Ter., for duty at that post, reporting by letter to the Commanding General, Department of the Missouri. Par. 2, S. O. 258, A. G. O., Washington, November 6, 1888.

Hoff, J. Van R., Captain and Assistant Surgeon, is granted leave of absence for one month, with permission to apply for an extension of one month. S. O. 134, Headquarters Department of the Missouri, Fort Leavenworth, Kan., November 1, 1888.

Price, Curtis E., Captain and Assistant Surgeon, is granted leave of absence for two months, with permission to apply for an extension of ten days. Par. 2, S. O. 257, A. G. O., Washington, November 3, 1888.

Wood, Marshall W., Captain and Assistant Surgeon, is granted leave of absence for one month, with permission to apply for an extension of ten days. Par. 2, S. O. 257, A. G. O., Washington, November 3, 1888.

Cochran, John J., Captain and Assistant Surgeon. By direction of the Secretary of War is relieved from temporary duty at Headquarters Division of the Pacific, and will report in person to the commanding officer, Fort Adams, R. I., for duty at that post. Par. 2, S. O. 256, A. G. O., Washington, November 2, 1888.

Bradley, Alfred E., First Lieutenant and Assistant Surgeon (recently appointed). By direction of the Secretary of War will report in person to the commanding officer, David's Island, New York, for duty at that depot, reporting by letter to the Superintendant of the Recruiting Service, New York City. Par. 14, S. O. 260, A. G. O., November 7, 1888.

Official List of Changes in the Medical Corps of the United States Navy for the week ending November 10, 1888.

Dickinson, D., Surgeon. Ordered to Naval Hospital, Mare Island, Cal.

Bradley, G. P., Surgeon. Detached from Naval Hospital, New York, and to Iroquois.

Persons, R. C., Surgeon. Detached from Army and Navy Hospital, Hot Springs, Ark., and to Naval Hospital, New York.

NORFLEET, ERNEST, Passed Assistant Surgeon. Detached from Naval Hospital, Mare Island, Cal., and to the Trenton.

HARRIS, H. N. T., Assistant Surgeon. Detached from Naval Hospital, Mare Island, Cal., and to the Kearsarge.

SAYRE, J. S., Assistant Surgeon. Ordered to examination for promotion.

BEYER, H. G., Passed Assistant Surgeon. Detached from Trenton, and granted six months leave, with permission to leave the United States.

PATRICK H. BRYANT and LUTHER L. VON WEDEKIND, commissioned Assistant Surgeons.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending November 10, 1888:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	27	8
Scarlet fever	157	24
Cerebro-spinal meningitis	1	0
Measles	161	7
Diphtheria	83	27
Small-pox	0	1
Yellow fever	0	0
Cholera	0	0

POISONING BY ARTIFICIAL MINERAL WATER.—Between thirty and forty cases of poisoning were reported several months ago in Rendsburg, Germany. Inquiry showed that only those were poisoned who drank freely of Selters water, and an examination of this water revealed the fact that it contained a very appreciable amount of arsenic. The water was a manufactured product, and had been imported from another city.

THE CONTAGIOUSNESS OF ALOPECIA.—The committee appointed by the Academy of Medicine in Paris, to consider the question of the contagiousness of alopecia areata, has just rendered its report. The rules enjoined upon those afflicted with this disease in the public schools, etc., could hardly be more rigorous if it were scabies which ailed the children, and indicate the conviction in the minds of the committee that this disease is contagious.—Philadelpha *Medical Times*.

EXCELLENT SENTIMENT BUT POOR SURGERY.—The following sensational story from the Atlanta *Journal* is going the rounds of the secular press:

"*Brave in the Face of Death.*—One day during the last part of the war Dr. Willis Westmoreland was dressing the wound of a soldier who had been shot in the neck near the carotid artery.

"Suddenly the blood-vessel gave way, and just as quickly the surgeon thrust his finger into the hole to stop the flow.

"'Doctor,' said he, 'what does that mean?'

"'It means death,' said the surgeon.

"'How long can I live?' asked the soldier, whose mind was perfectly clear.

"'Until I remove my finger,' said Dr. Westmoreland.

"'The soldier asked for pen and paper, wrote his will, wrote an affectionate letter to his wife, and, when these were done, said quietly:

"'Let it go.'

"The surgeon withdrew his finger, the blood rushed out, and soon the man was dead.

"The body of the brave fellow was buried in Oakland, and every year since Dr. Westmoreland has gone on Memorial Day and placed flowers on the grave. This year, when Memorial Day came, the doctor was at Salt Springs. He left the scene of gayety, came to Atlanta, and carried his tribute of flowers to the grave of one who was calm and brave in the very presence of death."

We hope this is not founded on fact. If so, it was bad surgery. Scientifically speaking, it would have appeared better to have tied the bleeding vessel in the wound, but it would have possibly spoiled a pathetic story.

ARTIFICIAL COLD FOR YELLOW-FEVER HOSPITALS.—Dr. M. S. Leslie, of Lexington, Ky., writes: "On the same principle as that employed in the artificial manufacture of ice, might there not be a sort of hospital constructed so as to reduce the temperature of the apartments occupied by the patients to about the freezing point, and thus contribute largely to the cure of those already suffering from yellow fever, as well as to the prevention of the disease in those who have been exposed to the poison?"

THE STORY OF MR. BAKER BROWN, as recently told by Mr. Tait in the *Hospital Gazette*, is perhaps unknown to most of our readers and it is worth publishing here. When one compares the persecution of Mr. Brown for cutting off an inconspicuous projection like the clitoris, with the tremendous applause which has accompanied the operation of removal of the ovaries, one marvels at the changes in professional opinion of to-day. "Some thirty years ago," writes Mr. Tait, "there lived and flourished in London a surgeon of great ability, Mr. Baker Brown, whose influence in the history of ovariotomy will be displayed in its appropriate place. Mr. Baker Brown was not a very accurate observer, nor a logical reasoner. He found that a number of semi-demented epileptics were habitual masturbators, and that the masturbation was, in women, chiefly effected by excitement of the mucous membrane on and around the clitoris. Jumping over two grave omissions in the syllogism, and putting the cart altogether before the horse, he arrived at the conclusion that removal of the clitoris would stop the pernicious habit, and therefore cure the epilepsy. He operated in an enormous number of cases, for epilepsy is very common, and patients and their guardians will submit to almost anything which promises a hope of relief. There can be no doubt that many cases were temporarily benefited, just as cases of epilepsy are benefited for a while by castration (in the male), removal of the uterine appendages (in women), and trephining (in both sexes). Besides, Mr. Baker Brown's operations had no mortality, and the reduction of the sexual distemper of a number of epileptics, even for a while, or to some extent, was of itself a benefit. But Mr. Brown carried his efforts to a most injudicious extent, due to the fact that he was suffering from very extensive cerebral softening, and really was incapable of forming a sound judgment. His subsequent illness and death proved this, and I have a large amount of documentary evidence in my possession, which some day will see the light, which will place the terrible story of this most unfortunate man in a light altogether different from that in which it has hitherto been regarded. As a result of the disease from which he suffered, he resisted the advices of his colleagues and the committee of his hospital, and he ran his hobby until he got into trouble with the Commissioners of Lunacy for a technical infringement of the conditions under which lunatics may be detained in places not licensed for their reception. This would have been of little consequence had he not been a successful ovariotomist, and had he not been pursued by a rival as relentless as he was cruel and persevering. The authorities of the Obstetrical Society were induced to take up the matter, and Mr. Baker Brown was expelled from the Society, a large part of the evidence against him being furnished from the common-place book of a rival who seemed to have been dogging his steps for years."

THERE IS SAID to be a barber's sign near the Palais Royal, Paris, bearing the following legend in the vernacular: "Callileucocapillaire water which colors the hair white. For the use of young physicians and magistrates."

Original Articles.

ON THE DIAGNOSIS OF DUODENAL ULCER.

By WILLIAM OSLER, M.D.,

PROFESSOR OF CLINICAL MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA.

It has recently been suggested by Bucquoy[1] that the duodenal is to be distinguished from the gastric ulcer by certain well-defined clinical characters. Dr. W. W. Johnston, of Washington, has reported[2] an interesting case which seems to bear out this author's statement. I have expressed myself somewhat sceptically on this point, although one of the nine cases which formed the subject of my recent paper[3] was regarded during life, by Dr. Palmer Howard, of Montreal, as probably duodenal, on much the same grounds as Bucquoy lays down.

Physiologically, the portion of the duodenum above the bile papilla belongs to the stomach. Peptic digestion only ceases where the acid chyme is neutralized by the bile. When we consider how limited is this region, and how close to the pyloric ring many gastric ulcers lie, it is not surprising that difficulty should exist in the diagnosis.

The points upon which Bucquoy lays the greatest stress in the diagnosis of the duodenal ulcer, are as follows:

First. Sudden intestinal hemorrhage in an apparently healthy person, which tends to recur and produce a profound anæmia. Hemorrhage from the stomach may precede or accompany the melæna.

Second. Pain in the right hypochondriac region coming on late; two or three hours after eating.

Third. Gastric crises of extreme violence; the hemorrhage being more apt to occur about the time of these attacks.

The following cases are of interest in connection with possible existence of duodenal ulcer.

Case I.—*Dyspepsia. Hæmatemesis and melæna in* 1870. *Repeated attacks during the past eighteen years, with the exception of the three years,* 1877–1880. *Frequent attacks of hemorrhage from the bowels without vomiting of blood. Severe gastralgia.*

Henry C——, upholsterer, aged forty, was brought to the Philadelphia Hospital by the ambulance, on January 4, 1888, in a condition of profound exhaustion. The next morning he gave the following account: For a month he had had diarrhœa, and on several occasions had passed blood in the stool, without any vomiting. On the night of January 1st, he vomited nearly two quarts of blood. On the 2d he remained in bed very much prostrated, and that night again vomited a large quantity of blood, "half a basinful," he said. On the 3d he had no vomiting, and on the evening of the 4th, when in hospital, he vomited three or four times and brought up clots of dark granular matter. On inspection, the patient was found to be profoundly anæmic and unable to sit up in bed without fainting; his skin was like alabaster; pulse 130, small; respiration 20; blood-count, 950,000 r.c. per c.mm. Hæmoglobin, twenty per cent.

The history which he gave was remarkable. He had been healthy as a young man, with the exception of dyspepsia. In February, 1870, he had a hemorrhage from the stomach and brought up, he says, two bowlfuls of blood, and also passed blood in the stool. During the next two years he had several attacks, and suffered constantly with pains. In 1873 he nearly died of hemorrhage, and during the next four years, three months did not pass without a recurrence. In 1877, he was four weeks in the Pennsylvania Hospital, having had profuse hemorrhage from bowels and stomach. He returned to France after this, and on August 10th had bleeding from the bowels. For the next three years he had no hemorrhage, though he was never free from uneasy sensations in stomach, and at times had attacks of severe pain.

In 1881 the hæmatemesis recurred, and since then he has had repeated attacks. In 1883 he was in the hospital sixty-five days; lost sixty-five pounds in weight, and was believed to have cancer of the stomach. From this time he had more or less gastric disturbance, consisting of pain after eating, usually delayed for several hours. At intervals of a few weeks there would occur severe gastric crises, in which the pain would be agonizing in character, shooting from the stomach, back, and sides; he vomited sometimes large quantities and occasionally had attacks of diarrhœa. When in hospital, in 1883, he was taught to wash out the stomach with a tube, and he has done it ever since, at intervals, with great benefit. He remained under observation until March 26th, and the blood condition was carefully studied, with the following results:

January 5th, r.b.c., 950,000 per c.mm.; 6th, 770,400; 7th, 1,053,000; 8th, 1,086,400; 9th, 1,175,000; 10th, 1,179,000; 12th, 816,400 (bleeding the night before); 13th, 1,034,400; 15th, 916,320; 19th, 1,300,000.

From this time the rate of increase was rapid. When he left the hospital the blood-count was over 3,500,000 per c.mm.

On January 14th he had a large movement of the bowels containing blood, but there was no vomiting. From this time on the bleeding ceased. His appetite became ravenous, and it was with the greatest difficulty that he could be confined to proper diet. Examination of the abdomen revealed slight distention; no tenderness; no trace of tumor. The abdominal walls were thick, and it was difficult to outline the stomach, the gastric tympany extending a hand's breath below the costal margin. The organ appeared to be slightly enlarged; liver dulness normal; splenic dulness not increased. There were the usual cardiac and arterial phenomena of profound anæmia. Throughout the month of February the improvement was very rapid. He gained in weight; began to have a little color and had no gastric distress, even after a full meal. He had diarrhœa at times; three or four stools in a day. Early in March he was anxious to go to work, and was with difficulty kept in hospital. He had no vomiting, and stated that he felt perfectly well with the exception of a slight weakness. He had a ravenous appetite, and I repeatedly had to warn him against eating too much. He returned to work March 26th, and through the spring and summer remained fairly well.

On August 4th the hemorrhage from the stomach recurred and continued four days. He lost much blood and grew rapidly weak. In the course of a week he returned to work, and on September 5th called to see me at my office, having come directly from the workshop. He was profoundly anæmic, extremely short of breath, and could scarcely get up the stairs. For nearly a week he had been passing blood from the bowels, without vomiting. He was admitted to the University Hospital September 5th. He complained of slight gastric distress, but had no bleeding until the 20th, when he vomited nearly a pint of blood, dark in color, mixed with food. The same evening he passed large quantities from the bowels. With the exception of weakness he insisted that he felt well, and was always asking for more to eat. There was no further vomiting during his stay in hospital, and his blood-count, which had been about 1,500,000 on October 8th, rose rapidly to nearly 3,000,000 per c.mm. He gained seven pounds in weight within a month.

---

[1] Archives Générales, April, May, and June, 1887.

[2] American Journal of the Medical Sciences, 1888, i.

[3] Canada Medical and Surgical Journal, March, 1887

On the 8th the examination of the abdomen gave results as follows: Somewhat dilated; uniformly tympanic; no tenderness; no tumor to be felt; obscure sense of increased resistance at a point midway between the navel and right costal margin; liver dulness from the sixth rib to costal margin.

He has periods of freedom from abdominal pain, but not of long duration. After a full meal he is at first comfortable, but in three or four hours there are uneasy sensations in the stomach, often positive pains, which may become severe. When the stomach is empty and the pain becomes intense, taking food, even a biscuit or half a glass of milk, will give relief. As stated, there is no epigastric tenderness, and he always locates the pain along a line from the ensiform cartilage to the spine of the left ilium.

CASE II.—*From 1869 dyspepsia and occasional attacks of gastralgia. In 1880 hæmatemesis and melæna. In 1882 slight melæna without vomiting. Since then repeated attacks of gastralgia.*—A. B——, aged forty, good family history; was delicate as a lad, but after the age of fourteen enjoyed the average health with the exception of dyspepsia, to which he was liable, and he would at times regurgitate food without discomfort or nausea. In 1869 he had gastric distress sufficient to make him at times press hard against the stomach; no nausea; no vomiting. With the exception of attacks of dyspepsia he remained well until September, 1876, when he had fever, and, during convalescence, violent attacks of gastralgia. These occurred sometimes with vomiting. He had more or less gastric distress until 1879, and he was believed at this time to have malarial gastralgia, and was ordered quinine and arsenic in large doses. In September, 1880, after a hard day's work, he returned home at 10 P.M., and had a great deal of gastric trouble, and before he went to bed regurgitated his food and, mixed with it, some black material. He slept well that night, and in the morning had a large bloody stool. That day he vomited a large quantity of blood and became very exsanguine. After this time the pain increased very much, but it was always relieved by a hearty meal.

In November and December he was in the hospital on the strictest diet, and lost in this time about forty pounds in weight. He improved after this, and in July, 1881, went abroad and was away for two years, during which time he had much discomfort but no very severe attacks of pain.

He consulted many of the leading physicians of Europe, and the diagnosis was uniformly gastric ulcer. While in Paris he had slight hemorrhage from the bowels without vomiting blood. He returned to this country in December, 1882, and has been working off and on ever since, but never entirely free from gastric distress, occasionally having severe attacks of pain.

In January, 1887, he had such an attack which lasted fourteen days, and lost twenty-eight pounds in weight. He has repeatedly had to take morphia in large doses to relieve the pain. The patient looks well; weighs one hundred and sixty-five pounds; tongue clean; good appetite; good digestion. Examination of the abdomen, negative; no tenderness; no tumor.

REMARKS.—These two cases have certain points in common. In the first place, the long duration; the symptoms in one instance recurring over a period of eighteen years; in the other at least twelve years. The peptic ulcer, gastric or duodenal, may be an exceedingly chronic malady, lasting ten, fifteen, twenty, or, according to Brinton, even thirty, years. Anatomical observations show that a large proportion of these ulcers heal, yet there are others which, from their general condition, can scarcely be repaired. The deep excavation, the size of a dollar-piece, with hard fibrous base, thickened peritoneal coating, and indurated edges, which we find so often in fatal cases, is an unlikely ulcer for cicatrization. The time element in these two instances gives no clue whatever to the situation of the ulcer.

The pain in gastric and in duodenal ulcers is very similar, with the exception of the time of onset, which, as a rule, in gastric ulcer more closely follows ingestion of food, while in the duodenal it is deferred two or three, or even four, hours. This is, however, an uncertain symptom.

In Case IX. of my series, close questioning elicited the most positive statement that food had no special influence, one way or the other, in inducing or in aggravating the pain, which was more likely to come on while the stomach was empty than subsequent to a meal.

The late onset of pain in duodenal ulcers has usually been attributed to the action of acid chyme passing out of the pylorus toward the close of gastric digestion. It is to be remembered, however, that the chyme passes continuously from the stomach, commencing, probably, within a half-hour after taking food. The increased acidity of the gastric contents toward the close of digestion may have something to do with it.

While perhaps too much stress has been laid upon this point in the differential diagnosis between gastric and duodenal ulcers, it does hold good in certain instances. A more important criterion, I think, is in the occurrence of gastric crises, agonizing attacks of colic, which seem to be more severe in the duodenal disease. A feature worthy of notice is the occurrence of severe gastralgic attacks at night.

Absolute immunity from all gastric distress in the intervals between taking food is more common in duodenal than in gastric ulcer. It is to be noted, in the cases here reported, that gastric distress has been more or less constant. A feature common to both ulcers is the prolonged interval of freedom. In Case VIII. of my series, a diagnosis of malarial gastralgia was made by an eminent clinician, based largely upon the fact that the patient had repeated periods of complete immunity from all symptoms, but followed by attacks of the most aggravating character.

The point upon which the greatest stress has been laid in the diagnosis of duodenal ulcers is the occurrence of melæna without hæmatemesis. Bucquoy and Johnston both hold that it can be recognized by this symptom alone. If so, the diagnosis in the patients whose history is given above is plain. The first case had repeatedly passed blood from the bowels without hemorrhage from the stomach, and the second on, at least, one occasion. As already stated, it was this symptom which, in Case VIII. of the series I have reported, led Dr. Palmer Howard to suggest the existence of duodenal ulcer. In the above-reported cases I should hesitate to give a positive diagnosis on this symptom alone, with the co-existence of such marked gastric disorder. In Johnston's case and in several of Bucquoy's patients, I grant that the conditions for a correct diagnosis were fulfilled, and I accept the importance of melæna alone as a valuable localizing index; but I submit that instances such as I have given illustrate the uncertainty, rather than the certainty, which still pertains to the diagnosis of duodenal ulcer.

CHROMIC ACID IN EXCESSIVE SWEATING.—A circular has been sent to all the Prussian Army medical officers, advocating chromic acid as an economical and efficient means of checking excessive perspiration. In hyperhydrosis of the feet the application of a ten-per-cent. solution, repeated every three or six weeks, is sufficient to prevent any inconvenience from this source.—*Medical Press.*

A NEW AND ONLY WAY OF RAISING THE EPIGLOTTIS.[1]

By BENJAMIN HOWARD, A.M., M.D., F.R.C.S. Edin.,

LONDON, ENGLAND.

The epiglottis, as regards its functions, from the time of Plato to that of Magendie was conspicuous as a subject of dispute. Respecting the epiglottis as a factor in apnœa, on the contrary, that which was taught at the first has been taught ever since, and is to-day everywhere the rule of universal practice. This teaching is, 1st, that in apnœa the epiglottis falls backward and closes the glottis. 2d. That the elevation of the epiglottis is the first thing in order and in importance, as without this, respiration, whether natural or artificial, is impracticable and the result fatal. 3d. The only way by which the epiglottis can be elevated is by means of the tongue; as the tongue is brought forward, the epiglottis is moved upward.

As a summary of results of prolonged and repeated investigations and experiments the author proposed to show:

1. The effect of traction of the tongue; what is done by it, and what is not done by it.

2. A new and only way of raising the epiglottis.

3. Some important changes in the relations of certain parts of the upper air-passages to each other induced by complete extension of the head and neck.

By the aid of a series of diagrams made by the author from sketches he had made from nature he then showed:

1. Contrary to general belief, traction of the tongue, however and whatever the force employed, does not and cannot raise the epiglottis, as supposed, because:

(*a*) The tractile force supposed to be exercised upon the epiglottis is arrested chiefly by the frænum linguæ, and through the muscular fibres within is expended upon the inferior maxilla, into the genial tubercles of which they are inserted.

(*b*) The surviving force is expended almost entirely upon, and intercepted by, the anterior pillars of the fauces.

(*c*) For any tractile force which might survive, a continuous and sufficient medium for its transmission to the epiglottis is wanting.

Proof.—The glosso-epiglottidean fossa being filled with water, the subject being so placed that the floor of that fossa is formed in part by the fallen epiglottis itself, traction upon the tongue, however forcible, does not cause the water to be spilled.

As the author had just been publishing an improved way of seizing the tongue for the above purpose, this discovery was a great disappointment and a great dilemma, as no other way of raising the epiglottis seemed to have ever been contemplated. After a search by no means easy nor short the author discovered,

2. The only way by which the epiglottis can be certainly raised, which is by extension of the head and neck. By this means its elevation is instant and complete.

Because (*a*) by a three-linked chain, of which the hyo-epiglottic ligament is the lower link, the body of the hyoid bone the central link, the combined genio-hyoidei and mylo-hyoidei muscles the upper link, the epiglottis is so coupled to the inferior maxilla, just where it has its greatest range of motion, that above a certain point, as the lower jaw is moved upward, the epiglottis instantly, irresistibly, and inevitably moves upward exactly in unison till it is erect.

The customary wrenching asunder the clinched teeth, in proportion as it depresses the body of the lower jaw, antagonizes a distinct effort of nature to maintain the elevation of the epiglottis, and specially favors, sometimes helps, sometimes greatly increases, its depression.

The author indicated on his diagrams the way in which other anatomical causes of obstruction, in addition to the epiglottis, respectively bar the air-way, for all of which he submitted a positive and complete remedy, and showed,

3. The way in which, by extension of the head and neck, carried to the utmost completeness, the backward fallen tongue, the velum palati, and uvula are all simultaneously shifted from the air-way, and the entire pharynx is enlarged throughout, as follows: (*a*) The tongue, the dorsum of which before fell by gravitation upon the then horizontal posterior wall of the pharynx, falls upon the now horizontal arch of the palate.

(*b*) The velum palati, by means of the great tension of the palato-pharyngei muscles, is pulled away from the posterior wall of the pharynx, the entire membrane being stretched tightly forward and downward behind part of the dorsum of the tongue, forming a partition which helps to shut the tongue out of the pharynx, and into the mouth, where it belongs, and with part of the dorsum forms the anterior wall of a now post-oral air-way, thus created and maintained.

(*c*) The pharynx, anteriorly, is stretched far forward by the extremely tense sterno-thyroidei muscles acting through the thyroid cartilage. By the semhyoidei and mylo-hyoidei muscles acting through the os hyoides, the base of the tongue and the velum palati are shifted forward in the manner already described, the posterior nares being shifted by the extension of the head by its occipito-vertebral articulation about sixty degrees.

Posteriorly, the wall of the pharynx is shifted back its whole length by the extension of the cervical vertebræ upon each other, in all about thirty degrees, the extension being particularly great just opposite the glottis.

Thus the upper air-way, which before was a tortuous angular, flaccid canal, barely, and if at all uncertainly, permeable, is made an enlarged, firm, but slightly curved tube, free throughout from the glottis to the nares.

The way to make complete extension of the head and neck.—Having, by bringing the patient to the edge of the table or bed, or by elevation of the chest, provided that the head may swing quite free, with one hand under the chin, and the other on the vertex, steadily but firmly carry the head backward and downward; the neck will share the motion, which must be continued until the utmost possible extension of both head and neck are obtained. Sometimes a slight extension or elevation of the chin merely will at once check stertor, or irregularity of breathing; but the extension, which can in no case do harm, should be always rather more than less than appears necessary. It should never be forgotten, however, that the full effects of extension, as above described can be secured with certainty only by making the extension complete as directed.

That the customary pulling forward of the tongue is followed by relief the author admits to be true in some cases, but in some cases only; the inversion of the entire body, the chucking under the chin, the jerking the angle of the jaw, in each of these the good done, and which was the only and all-sufficient reason for the habit, is an interesting corroboration. Each tended to raise the epiglottis, but the operators did not know it.

Further corroboration is in the familiar position instinctively assumed by the croupous, the diphtheritic, the asthmatic, the dying.

A diligent search has failed to discover a single record in which any observer states that by pulling forward the tongue he has seen the epiglottis raised, nor is there a single reference to anybody who is supposed to have seen it. On the contrary, the facts here submitted have all been many times examined, and have been verified by distinguished anatomists at demonstrations made by the author at the Royal College of Surgeons, England; at King's College Hospital, and at Guy's Hospital, London; and at the Hospitals la Pitié, and Salpetrière, Paris.

The position of complete extension enables certain operations on the throat and pharynx to be done in anæsthesia without the usual peril from drainage into the trachea. The sum of what has been submitted is:

---

[1] Abstract of a paper read before the Medical Society of London, October 22, 1888.

1. That, contrary to universal belief, traction of the tongue cannot raise the epiglottis.

2. By sufficient extension of the head and neck, whether by volition, instinct, reflex action, or by the effort of another, whether in the healthy, the dying, or the dead, the epiglottis is instantly, and beyond prevention, made completely erect.

3. By complete extension of the head and neck the tongue and velum are, as respiratory obstructions, simultaneously with the epiglottis, removed, and without a moment's delay the entire air-way can be straightened, enlarged, and made free throughout by the nearest person.

If syncope happens to be a chief or a secondary factor, this also thus gets the quickest and best correction.

The author expresses the hope, as he has the confident belief, that the facts submitted will be found to be permanent additions to our means of averting death, in which case it is not by the raising of the epiglottis. In the stage and the case in which the backward-fallen tongue happens to be the chief cause of obstruction, by pulling forward the tongue that cause of obstruction is removed, nothing more. There are other cases, other stages, in which it does no good at all. From over thirteen thousand fatal cases of asphyxia in England alone, the last three years, the author selected over one hundred unequivocally attributed to administration of anæsthetics, and in which, in every probability, the tongue was skilfully pulled forward in the recognized way, but they died. The author would be sorry to pretend to state of what they died; but he could not avoid the belief that, in each case, the epiglottis, in all probability, was not raised and continued uplifted till death was complete. It could but be thought a happy feature that instruments, the delays in getting them and in using them, the occasional violence and the invariable wounding with them, yet the utter helplessness without them, are, in the procedure submitted, so entirely superseded.

It was not pretended that never before had the epiglottis in this way been lifted. For more than twenty years the author himself had published and illustrated a certain position in the treatment of apnœa. This position inevitably opened the epiglottis, but he did not know it.

COMBINED COCAINE AND CHLOROFORM ANÆSTHESIA.—Dr. Obalinski advocates the use of cocaine injections as a means of aiding and prolonging chloroform narcosis. The patient first inhales chloroform up to the point of tolerance, which is usually reached in five or six minutes, with the consumption of four or five drachms of the anæsthetic. Then the author injects from one-half to three-quarters of a grain of cocaine at the seat of the proposed operation. After this injection no more chloroform is given, unless the operation is a very long one, in which case a little is inhaled from time to time at long intervals. The author has employed this method in several major operations with satisfaction, and, as the result of his experience, comes to the following conclusions: 1. This method combines all the advantages of general chloroform anæsthesia and of local anæsthesia from cocaine. 2. Vomiting very rarely occurs when the combined method is employed. 3. The awakening from the narcosis is more easy, and the after-effects are less pronounced.—*Journal de Médecine de Paris*, No. 7, 1888.

A DRUG ON THE MARKET.—The Madras government has so much difficulty in disposing of its cinchona febrifuge (the mixed alkaloids), that it is suggested that the drug be distributed to postmasters for sale, or given away to the poor, through the dispensaries and minor officials in malarial districts. The latter recommendation has been adopted.—*Philadelphia Medical Times*.

A SUCCESSFUL CASE OF COLO-COLOSTOMY.[1]

BY WILLY MEYER, M.D.,

SURGEON TO THE GERMAN HOSPITAL.

ALTHOUGH there is not much to be seen and felt on the patient whom I want to present to you to-night, I should nevertheless like to show her to you on account of the good result of the operation I performed on her three months ago. The operation was an enterostomy between the ascending and transverse colon, a colo-colostomy, for cancerous stricture at the hepatic curvature of the large intestine

Before describing the operation, allow me, Mr. President, to give a short history of the case. Mrs. F. S——, thirty-three years of age, mother of three children, had a miscarriage last January. A short time afterward she was attacked with painful cramps in the bowels, accompanied with constipation and vomiting. Suitable medical treatment gave temporary relief, but as other similar attacks soon followed upon the first, she entered the medical division of the German Hospital on March 28th. Here she was treated for chronic intestinal catarrh. Regulation of the diet and the administration of suitable drugs and large enemata improved her condition so much that, by the middle of May, she was able to leave the hospital. But the improvement did not last long. She went to stay at the house of an old friend, and as soon as she began to take the regular meals with the family, thus interrupting the diet to which she had been subjected, the old trouble returned, and in two days again she was admitted to the German Hospital (May 21st), and again was greatly benefited by the former treatment. But although retaining a fair appetite she constantly lost flesh. At that time I was kindly invited by Dr. L. Conrad, then physician in charge of the medical division, to see the patient with him, as local examination of the right groin discovered in it a resistance. We decided to make a thorough examination under ether. This revealed a hard, uneven, movable mass in the depth of the right hypogastric region, somewhat upward and inward from the anterior superior spine of the ileum, from which latter point a firm cord could be traced, extending downward and parallel with Poupart's ligament. Digital exploration by the vagina proved both parametria to be perfectly smooth. It was not very easy to make out the differential diagnosis. Of course we thought first and mostly of a malignant tumor of the gut; but the condition might also be explained by assuming that, in consequence of a subacute pericolitis, one of the lowest loops of the ileum might have become attached to the colon at a sharp angle, thus causing the recurrent intestinal obstruction. The long, firm cord, of which I spoke before, would then have been the thickened and elongated vermiform appendix.

Under the circumstances the patient seemed to require surgical interference, and for that purpose was transferred to my department.

The only operation advisable was that of opening the abdominal cavity, in order to ascertain the cause of the obstruction, and then to remove it if possible.

On July 2d I performed laparotomy in the region of the tumor, making my incision parallel with the linea alba. The incision, five inches long, divided the peritoneum in the same length. Then, searching with two fingers for the tumor, I was able without any difficulty to bring it into sight and in front of the abdominal wound. It was found that a little above the hepatic flexure of the colon there was an infiltrating cancer, and a great many smaller and larger secondary growths spread over the whole surface of the ascending colon. The long, hard cord, mentioned above as running parallel to Poupart's ligament, was an infiltrated (carcinomatous) ligamentum coli.

---

[1] Presented to the Society of German Physicians, September 28th, and the New York Surgical Society, October 10th, 1888.

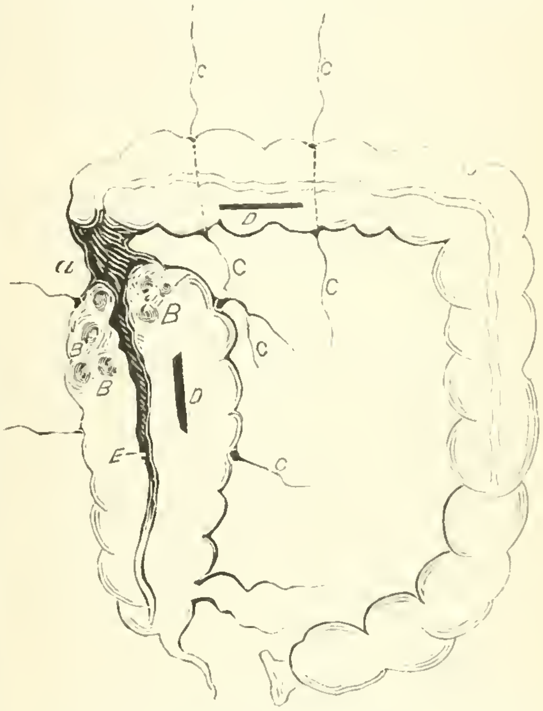
It was at once evident that a radical operation—resection of the diseased gut and uniting of both divided ends by suture—was out of the question, even if the patient's condition would have been more promising than it then was. The establishment, on the one hand, of an artificial anus in the lowest portion of the ileum, just before the ileo-cæcal valve, or, on the other hand, enterostomy, were the only procedures which could be taken into consideration.

In view of the great annoyance the patient would certainly have had to bear after the first operation, owing to the more or less liquid condition of the intestinal contents at the lower end of the ileum, I rejected the first plan, and decided to perform enterostomy. No doubt the most reasonable procedure would have been to establish the artificial stoma between the end of the ileum and the transverse colon, both being perfectly healthy, thus eliminating the entire diseased portion. But the retraction backward of the tumor (owing to its scirrhous nature) at the seat of the disease determined a bulging forward of the parts of the gut which lay just above and below the tumor. These protruding portions came so well forward and so near each other that it seemed an easy thing to attach the ascending to the transverse colon. By this union, moreover, not too long a part of the intestine would be excluded from the passage of the fæces. The danger of the stagnation of fæces would be thus diminished. I therefore resolved to perform the operation for colo-colostomy.

The whole operation was performed extraperitoneal, the abdominal wound and the intestine having been well protected by several layers of iodoform-gauze and flat aseptic sponges. I selected two parts of the gut, above and below the tumor (see figure) as far as possible from the growth, but easily adaptable to each other, pushed two strong catgut ligatures through the mesocolon, near the gut, at a distance of about three and a half inches on either side, taking care that before tying them temporarily the portion of the gut was well emptied of its contents by squeezing it with the fingers in a direction opposite to the location of the cancerous growth. Then I made a longitudinal incision of nearly two inches into both segments of the bowel, brought them together, and united them by a double row of a continuous catgut suture (Lembert's method). The posterior margin of the incision in the ascending colon was stitched to the posterior margin of the incision in the transverse colon from within outward, the mucous membrane not being included. After careful cleansing the parts were reduced, and the abdominal wound was closed. The peritoneum was stitched separately. An antiseptic dressing, held by broad strips of adhesive plaster, covered the wound, and a roller bandage compressed the abdomen. The patient was then brought to bed. There having been no loss of blood at all, the shock was very slight, although the operation lasted nearly two and a half hours.

Concerning the subsequent history there is not much to be said. Patient did not receive food in the first twenty-four hours. Then she was kept on liquid food and small doses of laudanum, three drops every two hours; two ice-bags covered the abdomen, as there was some pain. Temperature never arose above 100.2° F; the pulse was somewhat rapid in the first two days, ranging between 100 and 110 (probably the effect of the chloroform), afterward it was normal. On the second day icterus developed, gradually getting worse, and disappearing exactly two weeks after the operation. I do not hesitate to pronounce this as one of those rare forms of icterus known as hematogenous. First I feared that the reduced bowels might press in some undefinable way upon the ductus choledochus. But the patient being, apart from the icterus, in perfectly good condition, I soon came to the conclusion that the icteric discoloration of the skin and conjunctivæ was due to the reabsorption of the bloody serum that had filled the abdominal cavity at the time of the operation, and which, in order to save time, was not completely sponged out. (Lauenstein has seen the same kind of icterus upon a gastro-enterostomy [1]) On the eighth day after the operation the bowels moved without any trouble, and from that time did so regularly by the aid of a teaspoonful of castor-oil daily. When the first dressing was removed, on the eleventh day after the operation, the wound was closed and firmly united by primary union. Soon the patient's appetite became very good, she gained constantly and was allowed to leave the bed on the twenty-third day post operationem. She left the hospital on the 24th of August. Up to that time she had gained sixteen pounds, weighing one hundred and twenty-eight (to one hundred and twelve before the operation).

To-day she has a strong and healthy appearance. She eats anything, even German cabbage and salads, though, of course, this is without my sanction. Her bowels move every morning regularly, sometimes two and three times a day without help. She is cheerful, feels able to work, and weighs one hundred and forty-eight pounds, which means a gain of thirty-six pounds in three months. She was anxious to resume her former occupation of stewardess on the North German Lloyd steamer Elbe; but as I was opposed to this plan she is now going to fill a place as cook in a small family.[2] She has no idea that the tumor has not been removed, and believes herself perfectly cured. Only now and then she has a painful sensation in the right groin and a slight weakness in walking. The tumor has not increased in size since the operation; rather decreased, as far as we can judge by palpation, according to its nature as scirrhus.



A, Cancer: *B*, *B*, *B*, metastatic growths: *C*, *C*, temporary catgut ligatures; *D*, *D*, longitudinal incisions; *E*, ligamentum coli (infiltrated).

Of course, Mr. President, it is difficult to say whether the former stricture is now entirely unpassable by fæces. But as all the former troubles the patient complained of have disappeared, it is sure that the most part of the fæces, at least, are easily pushed forward by the way of the artificial opening.

My case shows very well the benefits of Woelfler's operation, and furthermore, that it can easily be applied in any portion of the intestinal tract with the same good result as in gastro-enterostomy.

---

[1] C. Lauenstein: Zur Anlegung der Magendünndarmfistel. Centralbl. für Chirurgie, 1888, p. 472.

[2] At time of correcting proof (November 10th) patient attends to cooking and general house-work since four weeks. She weighs 155 pounds (gain of 43).

It is well known that besides the stomach and jejunum the gall-bladder has been artificially and successfully connected with the jejunum in perfect obstruction of the ductus choledochus (cholecysto-enterostomy[1]), and the ileum with the colon[2] for stricture of the cæcum (ileo-colostomy.) As Dr. F. Lange, of this city, told me he sewed the ileum to the sigmoid curvature in a child of six months, who had invagination of the ileum into the ascending colon which could not be separated. It died four hours after the operation (May 1887), having been very low before the operation.

Woelfler says, in his first publication on gastro-enterostomy:[3] "Perhaps further experience will show that this plastic operation of the intestinal tract (gastro-enterostomy) will not only obviate the necessity of establishing a fistula of the intestine in cancer of the pylorus, but also in cancer of the gut." So far as I am aware, after a careful perusal of the literature of the subject, this is the second case (first by v. Hacker, l. c., for recurring cancer of cæcum) where the artificial intestinal anastomosis has been successfully performed for cancer of the intestines, and the first where union has been obtained between two different portions of the colon.

105 EAST FIFTY-NINTH STREET.

TEMPERAMENT AND DIATHESIS IN DISEASE.

By F. B. STEPHENSON, M.D.,

SURGEON, UNITED STATES NAVY.

STUDY and observation have given rise to the idea that knowledge of temperament and diathesis may be systematically applied to aid in the diagnosis, prognosis, and treatment of disease; and also in the discovery of personal physiological habit, or idiosyncrasy, in virtue of which certain disorders often appear. It is difficult, even if possible, to separate mind from body in this consideration, so intimately conjoined, if not identical in principle, are their modes of physiological action. We should not forget that the physician himself is influenced by such conditions, which modify his observing judgment, and remedial conduct.

According to the philosophers,[5] there are three normal temperaments:

1. The nutritive, of which typical forms are seen during infancy and youth, when nature is building up the individual. This is somewhat analogous to the lymphatic (*v. infra*), also recovering or sinking quickly. The feminine organism, in nervo-muscular mobility and weakness, resembles that of infancy.

2. The sexual. At the natural age for reproduction, growth of the person is subordinated to the formation of a future generation, influences tending thereto finding fullest fruition in an ennobling maternity.

3. The cerebral, controlling in later life. Intellect is now the force that decides, rather than those before mentioned.

As an instance of the nutritive unduly prolonged, we note obesity, which is unfavorable to reproduction or to mental energy; the converse relations of action often give corresponding results.

There are also masculine and feminine normal temperaments; but we find, not infrequently, the body of one united with mental and moral features of the other.

Predominating forms of temperament are, as it were, morbid states, deflections from the equilibrium of perfect life.

Resistance to the evolution of natural temperament, from whatever cause, may bring about disorder, perhaps disease.

During the various epochs of development, vicious activity, localized in divers organs, may occur, resulting in defects of normal growth in one part with morbid hypertrophy in others. Distinct pathological manifestations and moral affections belong to the different ages of the individual. Death from disease at these periods is characteristic; the child knows it not; the youth hopes to the last; the mature man resigns himself to the inevitable; while the advanced in years fall asleep, though loath to leave the loved ones.

Concerning what may be termed morbid temperaments (constitutions), the classifications of the ancients do not differ essentially from those of the moderns.

Although the sanguine, nervous, bilious, phlegmatic, and melancholic are generally recognized, we may for the present purpose, in illustration, consider only the sanguine, nervous, and phlegmatic.

1. The sanguine, which predisposes to violent physiological reactions, acute and excessive inflammations, complete evolution of disease, well-marked crises, plethora, hemorrhage, gout, rheumatism, quick and strong response to the use of remedies.

2. The nervous, where are found conditions favorable to intensifying of sensations, mental troubles, melancholia, hysteria, epilepsia, convulsive disorders, neuralgia, seasickness, insomnia, insanity, various neuroses, febrile delirium, lithiasis, dyspepsia, intestinal and hepatic obstruction. Morbid tendencies are increased by tea, tobacco, and alcohol. The course of disease is apt to be irregular, and its termination uncertain.

3. The phlegmatic, affording few manifestations beyond those essential to disease. Individuals of this somatic crasis show little evidence of pain; they do not feel much. A stolid physiology enables them to bear, with comparative ease, what would be agony for others. They may be fairly strong or impulsive in mind, but weak and easily exhausted in body; often the skin is pale, and the extremities cold. Reactions tending to health are slow and feeble. There is less power of resistance to acute maladies, and proneness toward disorders arising from, or connected with, low vital energy; such as strumous changes, catarrh, dropsy, especially asthenic and chronic processes and degenerations. Phthisis pulmonalis, scrofula, diabetes, and albuminuria from organic affection, seem to occur most frequently in persons of a lymphatic or nervo-lymphatic habit.

The above-named types are rarely seen distinct, but ordinarily shade into each other, appearing combined in varying proportions. Nevertheless one form usually predominates, while secondary indications have a meaning that merits interpretation: all are significant, in both normal and morbid activity. Characteristics of temperament are, as a rule, more marked in early life than during later years. Inherent modifying qualities belong to successive ages of the individual. Sex[1], occupation, seasons of the year, different centuries and historic epochs, race, and nationality, seem at times to be almost synonyms for temperament. Scandinavians are generally phlegmatic in bodily function, and slow in mental action. The volatile Celtic nature lacks the solidity of Saxon strength. A nervo-choleric manner belongs to the French. Acute manifestations of disease are common among the Italians, especially south of Florence, there is an intensity of all vital processes.[1] Idiosyncrasy may be regarded as a very special temperament. The occurrence of accidents may be due to definite physical or mental qualities. Diseases find congenial lodgment with particular temperaments; or, one has the diseases of one's temperament.[2] Disturbance of the balance of health, bodily or mental, brings on diseases which are of more gravity, because of the organs being already enfeebled by temperamental departure from normal form or perfect type.

[1] Characters which appear late in life in one sex are transmitted exclusively to the same sex.—Darwin.

Diathesis may be regarded as an aberration of nutritive processes. As typical we mention the strumous, rheumatic, and gouty.

1. The strumous (scrofulosis, tuberculosis) predisposition, very marked in early life, is often noticed in an organization generally delicate, of nervous temperament. It may be indicated by apparently slight caries, fragile or easily decaying teeth; chronic inflammations of joints, serous membranes, and connective tissue; phlebitis, long-continued discharges from mucous surfaces, and impetiginous eruptions. In youth scrofula is observed, the same person in more advanced life showing signs of tubercle. Hyperopia is frequent in offspring of such parentage; they readily appear prematurely old. Favorable conditions may cause an outbreak of unmistakable tuberculosis, which may also come on in connection with, or as a sequence of, syphilis, cancer, and nephritis. Sterility is sometimes due to tubercle in the ovaries or Fallopian tubes, with or without evidence of inflammation. Uncontrollable passion for alcoholic drinks (with its indirect dangers, as exposure, accidents, etc.), phthisis, neuralgia, epilepsia, paralysis, and insanity have been noticed, seemingly as complementary manifestations of this diathesis; derangements of mind and body thus replace each other. Composite portraiture is of use in establishing a diathetic type, *e.g.*, of phthisis.

2. In one of rheumatic habit, most pronounced in mature age, we expect various localizations of the *materies peccans* in the brain, heart, joints, and serous membranes, connective tissue seeming to be specially implicated. As diathetic alternates may be mentioned arthritis, pericarditis, chronic blepharitis, iritis, laryngitis, bronchitis (acute or chronic), meningitis, cerebritis, insanity, hysteria, chorea, partial paresis, erysipelas, herpes, pityriasis, erythema nodosum, itching of integuments without apparent lesion, and chronic diarrhœa. Changes of weather are noticed more quickly by persons of this tendency.

The quick healing of herpes cervicis uteri brings to mind the like in regard to cancer; fatal carcinoma has been observed to follow eczema. It appears that cancer occurs by preference in one of rheumatic disposition, as tubercle with the lymphatic. "Erysipelas has been known to cure insanity,"[3] it is stated; but we should prefer to say that erysipelas was the diathetic alternate of such insanity.

As a possible example, the following is presented: A woman, in circumstances of fair living, had been affected with chronic bronchitis and slight cervical endometritis. After a month's treatment (with drugs and local uterine applications) these diseased conditions had disappeared; but œdema then occurred, more or less transient, in divers parts, with occasional emesis, hysterical symptoms, semi-coma, etc.[4] The bronchitis, and other localized troubles, had evidently served as an conduit for the materies morbi, or malign influence of, we may suppose, diathetic origin. It may not always be wise to stop (cure?) a slight discharge.

[1] Rome in Winter, and the Tuscan Hills in Summer, by David Young, M D.

[2] Nouveau Dict. de Médecine.

[3] The New York Medical Journal, December 17, 1887.

[4] Some Unsolved Clinical Problems. The New York Medical Journal, May 7, 1887.

3. The gouty diathesis, usually an apanage of full age, presents many features similar to those of the rheumatic. Among the probable forms of alternate manifestation we give, as illustrative, anæmia, hypochondria, hysteria, chorea, irrepressible temper,[1] acute meningitis, neuritis, neurotic disturbances, migraine, localized paralysis, disordered action of the heart, continuous spasms or convulsive twitchings, urticaria,[2] erythema, eczema, psoriasis, asthma, dyspepsia (with grainy or fissured tongue), gastritis, hepatic and intestinal disorders, diabetes, nephritis, cystitis, gravel, calculus, and inflammations of the smaller joints. One form can, hereditarily, give rise to another, often not easy to recognize. As in the consideration of temperament, so, in relation to the habits of the body, varied diathetic interminglings should be taken into account when examining individual cases.

We may regard the foregoing as a number of illustrative alternating symptoms due to the same basic cause; when one portion of the disease wave goes up, a corresponding fall takes place elsewhere (metastasis). One of these diathetic alternates does not produce the other, but all have similar genetic relation. under the laws of organization; and appear in the same person or in kinsman of various degrees. Investigation of such physiological connection might lead to the simplifying of nosonomy.

There seems. moreover, to be a difference of susceptibility to disease in individuals, families, and races, quite irrespective of temperament and diathesis.

A diathesis may arise in the individual. lead to the formation of a cachexia, become hereditary, be transformed or destroyed by hygienic measures, or through selection of sexual union in transmission of life to another generation. It may be modified by particular diseases: scarlatina thus develops an incurable eczema; or a long fever works a favorable change in some inveterate complaint. The irregularities of such ailments as whooping-cough and variola might seem more clear when viewed in connection with constitutional peculiarities. Lack of perfect development in one part of the organism suggests the same in others. A half-formed palate may coincide with a weak mind depending upon an unfinished brain. Mental moods are affected according to the stages of these diathetic morbid processes.

Diathesis may be looked upon as a soil in relation to the production of disorder; and temperament comparable with atmospheric conditions, considered the means through which exciting causes act, or gain access—it is the proper physiognomy of each person.

Temperaments and diatheses being combined in different and varying proportions, render more complex the problem as to diagnosis, prognosis, and treatment; but it is not annihilated by ignoring facts.

In diagnosis, we may be better able to judge the real value of symptoms by remembering that indications of temperament and diathesis, as well as signs of disease, vary with climate. social surroundings,[3] and political eras. Families, communities, and races may become comparatively safe, through inheritance, a disease-virus losing original force in successive generations. Such constitutional states become known by heredity, atavism, examination of other consanguineous members of the family,[4] evidence of former disease. intolerance of certain articles of food, characteristics of gait, (limping),[1] physiognomy, and environments (circumstances in which diseases arise, *i.e.*, cause). By these the course of physiologic action in any given idiocrasy is apt to be modified, hastened, or retarded. When a disease does not pass through its usual regular series of changes, some perturbing morbid habitus, permanent or transient, is to be suspected. Passing mental humors, whims, etc., are sometimes of importance; *e.g.*, quietness, or depression (*tristesse*) may presage bodily sickness (fever); or, unnatural activity may portend grave illness. Irritability of pulse, nerve, and brain, frequently depends on weakness. The alteration of moral manifestations is in direct ratio to changes in corresponding organs, the condition of which may furnish the observer a measure of the disturbance in cerebration. Singular appetites are noticed in certain disorders. The vague "something" termed malaria seems to modify the temperature in other diseases, so as to cause sudden and great variation. When, from any cause, the system is debilitated, this influence is apt to show itself. Transitory thermal states modify indications of morbid action. Axillary adenitis is believed to be an early sign of pulmonary phthisis.

---

[1] Anatomy and Physiology in Character, by Furneaux and Jordan, p 66.

[2] Urticaria and migraine seem to be related as to their origin, and to belong to the same diathetic stock.—Rapin, Boston Medical and Surgical Journal, July 7, 1887, p. 22.

[3] It appears that effluvia from one set, or one race of man is poisonous to others. The lower animals have similar relations with themselves, and toward man.—Darwin.

After talking with physicians of actual experience in the matter, it seems probable that some of the commonly received statements alleging immunity of negroes, as such, from certain diseases lack logical support in fact. Dr Woodward (quoted by Dr. E. N. Whittier) gives, for typhoid fever: White mortality, 35 89 per cent.; negro mortality, 55.68 per cent. Typho-malarial fever: White morality, 8.13 per cent; negro mortality, 17.37 per cent.

[4] Family Predisposition to Fractures. Boston Medical and Surgical Journal, July 7, 1887, p. 22.

Cancer usually occurs in mature or old age, and is regarded as an affection of the white race, being rarely observed in negroes. Wounds (of bones and soft parts) in course of repair are influenced by temperament and diathesis; they are also modified by acute infectious maladies.[2]

Mutilations affect physical and mental development, and alter native inclinations, thus showing their material foundation. Moral dispositions with troubles of the chest are not the same as in abdominal disorders. A mild continued fever enlivens the spirits, causes one to see life in a more genial mood; and unusual mental qualities often appear in the course of active disease.

As to prognosis, the indications of temperament may enable one to decide more accurately the probable intensity of pathologic activity. With a certain diathesis we expect a congruous departure from the typical evolution of any particular malady, or repetitions of morbid processes. Accidental causes (a strain, blow, or fall) sometimes excite well-marked phenomena, bring on an attack of gout, rheumatism, or strumous inflammation in persons of the respective peculiar generative modus. With individuals of some blood connections certain diseases are likely to occur at definite periods of life, by heredity. Functional troubles of little importance, perhaps, in an otherwise healthy body, may, in peculiar diathetic conditions, become the forerunners of serious organic lesion, or end in cachexia. Each one has his strong and his weak part, with relative predominance of physiologic action. Very great activity in any particular system may announce change of highest moment to the whole economy. Personal habit in conduct of life, previous and present occupation (muscular or mental, indoors or out), may favor illness, by over- or under-work of certain organs. In the ability to resist forces inimical to health, and bear the strain of life, some men seem to be made of granite, some of marble, some indeed of clay.

Treatment.—The necessity for rational medicine is apparent when care of the sick becomes a duty. Practitioners know that individuals are differently affected by remedial measures (drugs, diet, external applications, exercise, travel, etc.); but might not much in this way be scientifically formulated, enabling one to foresee, instead of waiting to grope along, in each case, as symptoms arise?

Temperament may suggest diathesis; as the nervous, the strumous. A person of any diathesis (strumous, *e.g.*), properly cared for, may escape positive disease, to which another, in untoward circumstances, would, almost of a moral certainty, fall victim. Inasmuch as scrofula of youth is often a precursor of phthisis in mature age, efforts at prophylaxis are self-suggested.

Diathesis is to be combated by cutting off its supplies, factors, and conditions of causation. Physiognomy, properly based on anatomical and emotional data, as showing temperament and diathesis, may indicate ability to undergo treatment or operation. A patient of nervous type should exhibit more excitement than one of different organization. Neuralgia in such a one may cause a catarrh which will follow the phases of the nerve trouble. Neurotic persons often see mountains in mole-hills, and are annoyed by interior impressions. Relief may frequently be obtained through skilfully directing their attention away from the seat of alleged disease.

Asthma often comes on as eczema disappears; thus a hint is furnished for the conduct of the case. The effect of previous medication should not be forgotten. Untimely measures, the stoppage of habitual discharges (diarrhœa, hæmorrhoids, dermal exudations), or periodic migraine, by active treatment, without thorough knowledge of previous history, may cause the disappearance (so-called cure) of a comparatively harmless form of diathetic manifestation, only to be followed by some other perhaps more dangerous, or by grave perturbation of the general health. Hæmorrhoids, bronchitis, and headache have been observed to replace each other, one being always present. It is stated that, in the case of the Duchess of Cumberland, after heroic treatment for articular rheumatism, a tendency to mental disturbance was developed; later she became insane.[1]

In practice the recognition of blended diathesis is often more useful than an elaborate physical diagnosis.[2] The significance of idiosyncrasy, and its bearing upon treatment, has not received from specialists the consideration its importance demands.[3] A knowledge of the phenomena of health and comparative health, may be made more exact by considering those of disease.

It is believed that alcohol, mercury, and lead favor the outbreak of hysterical symptoms in those predisposed; the influence of railroad accidents (shock), etc., may be borne in mind. Parasitism, if often a sign of temperament, seldom annoys some individuals, and when so, during a very short time only—the soil is not propitious. Care of the same maladies properly varies in different climates. It is recorded that in its course intermittent fever has been destroyed by a determinate number of paroxysms,[4] without specific treatment.

In regard to children, unusual thought and management are necessary, inasmuch as their tissues and force are more impressionable, and pathological conditions tend to become general with more rapidity than in adults.

Immunity from disease and capacity for work (of both body and mind) depend greatly upon the quality of food, and its physiological fitness of ingestion as to time and regularity. Many individuals seem able to use alcoholic and other stimulants without apparent shortening of life or serious inconvenience; but in some instances a shattered economy or premature death is the result. Irregularities of life (errors of diet, and of passion) add to innate aberrations from the normal type. Tendency to physical disorders, outbreaks of anger, and morbid modes of thought, may be lessened by appropriate sustenance. Bulky food engenders slowness and rudeness in motion and intellection. Particular substances may be employed to further definite kinds of product. Taking of exercise, for purposes of health, should be modified according to temperament, climate, and the circumstances of the individual in view.[5]

The athletic régime is not suited for those who work chiefly with their brains, since it tends to increase rather the grosser forces of the economy. Intellectual labors diminish, relatively, muscular energy; the converse appears equally true. Mental medicine may advantageously accompany the physical. The proper therapeutics of gout should be based upon the study of the history of generations and races. Anyone hereditarily or diathetically inclined to disease might be wisely warned concerning probable ailments, particularly of brain, heart, lungs, and intestines.[1]

[5] Physiologie des exercices du corps, par le Dr. Ferdinand Lagrange.

The degree to which a person, in the various parts of body and manifestations of mind, has developed in the line toward perfection, may be significant as a guide in forecasting ability to withstand the wear and tear of life, or the strain of disease.[2]

Although the ultimate constituents of different individuals are the same, their proportion, manner of combination, and mode of action require anticipation of unlike effects under stress of the various demands of life—the willow cannot replace the oak.

Physical and mental degeneracy may result from incompatible or unphysiologic unions[3] (marriage) between those of similar or nearly allied temperaments and diatheses. Reproduction of undesirable characters, corporeal or psychic, might be avoided by consciously intelligent choice with respect to the significance of organization and inheritance. Political law is of slight effect in such matters. Knowledge, education, and an enlightened self-interest are the potent means. Upon man is bestowed the power of procreation, and with this intellect, to enable him to discover and obey the conditions necessary for transmitting a healthy organism to his posterity.[4] There is nothing really accidental in human nature, or other nature. Servility as to doctrine is sad in all things, but in medicine or physiology it is more dangerous than elsewhere, because it may hazard the life or welfare of the individual.[5] A knowledge of disease must be supplemented by careful study of the patient[6]—of man well and man sick—in various degrees of evolution, approximating more or less the normal type. In the application of the afore-mentioned ways of thinking, light may be thrown upon the formation of ideas, and a basis for moral conduct offered.

Temperament and diathesis might furnish data whereon to found timely advice for the prevention of illness. Hygiene, directed by physicians imbued with a scientific spirit, may be made vastly efficacious for the physical, mental, and moral improvement of animate beings.[7]

Comparable with the large dosing of late modern, half-learned practitioners, specialism forces unscientific measures upon the trusting sufferer. Sugar (diabetes), or albumen (nephritis), seems less in consequence (or mere sequence) of active treatment, with a chemical examination. The time that the patient's life may have been shortened through eager meddlesomeness, is not so conspicuous.[8]

Since the history of medicine shows fashions in treatment which succeed each other, and sometimes reappear in a following generation, the idea is forced upon our attention that a more perfect knowledge of physiology would reveal a better founded, more correct course of action.[9] Strict attention to the laws of evidence would enable us to discover truth, while avoiding fallacious inferences.[1] "The thorough medical mind requires not only accurate data, but the digested facts which nourish thought." "Truth is often reached through relations the least obvious to common observation."

The physician and others may advantageously learn the limit of their personal force, in both health and sickness, in order to obtain best results from effort.

A wise practitioner is an intelligent observer and comparer of things, searching for the conditions (cause) and natural history of disease, trying to find means of prevention,[2] guiding self-limited maladies toward a desired end, knowing when and how to act (or hold his hand from meddling), in aiding the economy to throw off morbific matters and resist unhealthful influences. Anyone with a panacea may be looked upon as a quack or an enthusiast—both as ignorant. In order to rightly use remedial agents, we should first know the effects produced thereby on all the organs and functions of the healthy body (therapeutic physiology).[3]

When human art can no longer help toward life, the duty of making easy the passage of the weakening body and conscious mind to repose in nature's sleep becomes apparent.

We may observe that the study of temperament and diathesis has been, in late years, comparatively neglected, whereas particular organs, and individual modes of morbific action, have received special attention. Nevertheless, a knowledge of the underlying, far-reaching influences that modify both natural and diseased function is requisite to the full understanding of physiology and pathology;[4] even as a large chart is needed by the world-navigator at times, though one showing more details is used when he draws near the coast; the latter is more thoroughly comprehended because of the general principles learned from the former. It is said that the present advanced condition of electro-dynamics has been attained in such a short time, because science had been evolved before art had wandered through long ages of vague and unsatisfactory empiricism.[5] May this idea be applied to medicine?

While, in many directions, the literature of modern medicine is rich with new and valuable information, the student of ancient physic can find much to guide him amid the maze of current professional writings.[6] To those who imagine that nothing is of worth save what recent science has brought to light, we commend the following, from an eminent practitioner: "Whoever, rejecting and disdaining the past, tries other principles (than those of which the profession has long been in possession), and pretends to have found something new, deceives himself, and deceives others.[7]

A Double Pyosalpinx Cured by Aspiration.—Mr. R. H. Bourchier Nicholson deserves thanks for reporting a case (*British Medical Journal*) in which he diagnosticated double pyosalpinx, removed several ounces of pus by the aspirator through the vagina, and cured the case. He was advised to do laparotomy, which would have been "a more brilliant operation," but he demonstrated that such a procedure was not needed.

Acetic Acid as a Disinfectant in Midwifery.—Dr. F. Engelmann, being much impressed by the numerous fatal cases which are constantly occurring from the employment of intra-uterine injections in obstetrical practice, and feeling that there is doubt whether they ought not to be given up, brings before the profession another antiseptic which he has used for the last two years in a large number of cases, and which has given him excellent results—acetic acid. Some years ago he was led to use and to recommend the employment of acetic acid in diphtheria, and he is convinced that it possesses antiseptic properties in as high a degree as carbolic acid itself, and has at the same time the great advantage of being non-injurious, even when used in a tolerably concentrated form; besides, it has a decidedly styptic effect, and this is an additional advantage in obstetric practice. Again, acetic acid is very diffusible, thus penetrating the tissues to a much greater extent than most other antiseptics. Corrosive sublimate, as is well-known, forms insoluble albuminoid compounds on the surface, and thus does not act upon the deeper parts of the tissues. In one respect acetic acid is similar to corrosive sublimate, viz., in its action on instruments; but the latter is the more prejudicial of the two. The forceps may remain for a quarter of an hour in a three per cent. solution of acetic acid without being injured. The irrigator is, however, liable to be affected by the prolonged use of acetic acid solutions. It should be remarked that the hands must be washed twice after using acetic acid, as of course soap will not dissolve where this is present. The skin is rendered peculiarly soft and pleasant to the feel. As to the strength to be used, Dr. Engelmann, as a rule, employs a three per cent solution, but he has sometimes employed a solution as strong as five per cent.; this, however, is apt to cause a smarting sensation in any spot where the surface is broken. All the cases in which acetic acid was used recovered without abnormal rise of temperature.—*The Lancet.*

The Destruction of Micro-organisms in the Blood.—Dr. v. Fodor has made a number of experiments by injecting bacteria into the veins to determine the part taken by the blood in the destruction of micro-organisms. He had shown in a previous communication that hundreds of millions of non-pathological bacteria injected into the blood completely disappeared from it in the course of a few hours. By further experiments he showed that this power of the blood to destroy bacteria was not diminished by a moderate degree of anæmia, but was lessened by dilution of the blood with water so far that the bacteria were destroyed more slowly and with greater difficulty. Even pathogenic bacteria disappear rapidly out of the blood, for example, typhoid bacilli, which even a few hours after injection are no longer demonstrable in the blood, while the animals are in some cases simultaneously infected by the injected material, and die with symptoms identical with those of typhoid. Anthrax bacilli injected in large quantities disappear within four hours, but within from twenty to forty-four hours they again appear in the blood, and the animal dies. In the period in which it is free from bacilli the blood contains, so far as the negative injection experiments show, no material producing anthrax; this is the best proof that it is the bacilli that produce the disease. In the same period, however, in which the blood is free from bacilli, in the internal organs (spleen, liver, kidneys) they are constantly present, from which it is evident that the pathological development of anthrax does not take place in the blood, but in the internal organs. Anthrax is not a blood disease, but the blood is rather the protector of the organism against the pathogenic bacteria. A very small quantity of anthrax material is not lethal, and further, the rapidity with which the disease is fatal is in direct proportion to the quantity of injected material. According to von Fodor, the bacilli injected into the blood are destroyed by it; some, however, reach the organs and there develop. When the colonies steadily multiply in these parts, then the blood, the chemical constitution of which is changed thereby, is no longer able to destroy the bacilli that are present in it.—*The Medical Press.*

Oxygen in the Capillary Bronchitis of Children.—Dr. Sinainski gives some notes of a case of capillary bronchitis in a child a year and a half old, which seemed likely to prove fatal, where oxygen exerted a rapid and beneficial effect, resulting in complete recovery (*The Lancet*). Hot baths, ipecacuanha, and emetics of sulphate of zinc, sulphate of copper, and apomorphia, had been tried, but the pulse was decreasing, and the child was growing more cyanotic and breathing with more and more difficulty. Three or four inspirations of oxygen produced a marked change, the breathing becoming easier and the cyanosis disappearing. The next day the child presented quite a different aspect. Tonics, expectorants, and stimulants were given, and in about four days' time the patient had quite recovered. Dr. Sinainski thinks that in apparently hopeless cases, where there are signs that the blood is not sufficiently oxygenated, the inhalation of oxygen presents us with a means of obviating the danger arising from that source, and in that way of perhaps saving the patient's life.

The Streptococcus Pyogenes found in Healthy Saliva.—Of one hundred and twenty-seven healthy individuals examined by Netter seven times, a micro-organism having the characters and behavior of the streptococcus pyogenes of Rosenbach was found in the saliva. In previous researches the author had found in healthy saliva Friedländer's microbe four times out of one hundred examinations, and Fraenkel's micrococcus in twenty per cent. of the number of individuals examined, and this without any of the examined having had pneumonia. The presence of this streptococcus pyogenes in the mouth may give some explanation of the frequency of suppurative inflammations in the course of scarlatina, diphtheria, and other pharyngeal diseases. So long as the epithelium is intact the microbe does not reveal its presence; it only becomes dangerous when an entrance for it into the tissues is effected.

On the Value of Pilocarpine in Pregnancy, Labor, and the Lying-in State.—At a recent meeting of the Obstetrical Society of London (*The British Medical Journal*, October 13, 1888), Dr. John Phillips read a paper on this subject. He treated the questions at issue under five heads: (1) The use of pilocarpine as an abortive; (2) for the induction of premature labor; (3) intra-partum; (4) post-partum and during the puerperium, and (5) in albuminuria with or without eclampsia. Seven cases had been experimented upon and the results given in detail. Forty-eight cases under the second heading had been collected from all sources, of which twenty-seven had been arranged in two tables, while two original cases had been appended in full. The author concluded that five only of these could be considered as unqualified successes, and thought that pilocarpine was able in a certain number of cases to induce labor, but that it was not in any way reliable as an ecbolic; those cases in which there was a tendency to premature termination of pregnancy being most suitable for its administration. Pilocarpine intra-partum was considered under three heads: (*a*) The "latent period" of labor; (*b*) the dilating stage of labor; (*c*) the expulsive stage of labor. Five instances occurred in the author's practice, and in one sphygmographic tracings were taken at various intervals. The result of thirty-nine cases was worked out, twenty-eight being successes, and eleven failures. The author concluded that during the dilating and expulsive stages of labor pilocarpine was equally productive of increase and intensification of labor-pains with ergot, but with more certainty of action and with none of its ill-effects. Cases of simple uterine inertia were the most suitable for its administration. The drug was useless post-partum and to stay hemorrhage. In a third table the results of thirty-nine published cases of puerperal eclampsia were given, with recovery of thirty-one mothers and eight maternal deaths, or 20.5 per cent. Although good effects were produced in twenty-eight cases, yet in nine such dangerous symptoms manifested themselves that the author felt bound to warn others against its use, especially when coma was pronounced. He recommended bleeding in conjunction with pilocarpine where it would not act alone, and adduced evidence to show that the mortality was not greater under this mode of treatment than in any other.

The Urine after Intermittent Fever.—According to the Paris correspondent of *The Lancet*, Professor Bouchard presented to the Academy of Medicine a note for Dr. Mossé, of Montpellier, on the "Composition of the Urine after Intermittent Fever." It is known that Professor Verneuil had drawn attention to the existence of glycosuria consecutively to paludism. Dr. Mossé, from observations made in a hospital where cases of intermittent fever are frequent, was able to prove that glycosuria occurred only exceptionally in patients having or having had intermittent fever. It did not appear to the author even that paludal intoxication had any kind of influence on the development of diabetes, the coexistence of the two maladies being a pure coincidence. Dr. Mossé has established, on the other hand, consecutively to marsh fever, an acute form of polyuria, the excretion amounting to ten litres of urine in the twenty-four hours. This polyuria, free from azoturia, would approach the polyuria of convalescence, and should not be considered critical.

Toxicity of Alcohol.—Dr. Laborde has made a communication to the Paris Academy of Medicine, on "Alcohol and its Toxicity." He referred particularly to the toxic substances contained in wine, brandy, and liqueurs. He remarked that the question of alcoholism is becoming every day more and more important. At the present time it may be estimated that the maladies due to alcoholic drinks constitute one-fourth at least of the diseases observed in France. The author studied the subject from a scientific point of view only, and carried out researches with the specimens obtained from the Municipal Laboratory, assisted by Dr. Magnan, well known for his researches with the essence of absinthe. It is in the manufacture of "bouquets," which give the wines their flavor, that the adulterations are practised. They are known in commerce under the terms of "huiles de vin Françaises," and "huiles de vin Allemandes;" the latter are mostly employed because they are more active. MM. Laborde and Magnan studied the toxicity of these substances by injecting them into the veins of dogs. They caused the death of these animals after having produced symptoms of excitement followed by nervous prostration and great difficulty of respiration. These substances are toxic in an extreme degree. Even alcohols are adulterated with odoriferous substances which mask the alcohols of bad flavor. Dr. Laborde had particularly studied furfurol, the odor of which is very agreeable, being similar to that of cinnamon or bitter almonds. The intravenous injection of furfurol produces in a dog an attack of epilepsy and then kills it. Liqueurs are also adulterated with analogous substances. The salicylate of aldehyde is substituted for the essence of the "queen of the meadows." It is found in vermuth, in bitters, and in whiskey. It is a colorless liquid, reddening when exposed to the air, and is of a very agreeable aromatic odor. Like furfurol, it kills dogs after having produced epileptiform attacks. As regards the salicylate of methyl, which is substituted for the essence of winter-green, it does not cause epileptic fits, but it produces rigidity and trembling, which also lead to death. Hence Dr. Magnan now recognizes that divers adulterated alcoholic drinks can produce epilepsy as well as absinthe, and it must be admitted that a still greater number have a baneful action on the nervous system.—Paris Correspondent of *The Lancet.*

The Prognosis in Syphilitic Diseases of the Nervous System.—Professor Naunyn has collected three hundred and twenty-five cases of nervous affections due to syphilis, one hundred and fifty-five (forty eight per cent.) of which were cured, and one hundred and seventy (thirty-two per cent.) in nowise benefited. Cases of epilepsy yielded the best results. Similar good results were obtained in neuralgic affections and paralyses of the basal cerebral nerves. Poor results were obtained in monoplegia, hemiplegia, and paraplegia. The treatment, if beneficial, will manifest itself immediately. If by the end of the first week after the administration of iodide of potassium, and the end of the second week after energetic mercurial treatment no benefit is obtained, then the outlook is hopeless. Any benefit derived from the specific treatment is first seen in improvement of the general condition. Heroic medication is necessary. Inunction is preferred in the administration of mercury.—*Sacramento Medical Times.*
